Guide to authors

● Review articles should be aimed at a relatively wide readership. Many reviews are invited, but submitted articles may also be accepted; it is advisable to consult us before writing a review article.

● Articles may be up to 3,000 words long with at most six displayed items (figures and tables); they are reports of major research developments.

● Letters are brief reports of original research of unusual and wide interest, not in general longer than 1,000 words; they have at most three or four displayed items.

● 'Matters Arising' permits short discussion (up to 300 words) of papers that have recently appeared in *Nature*.

Articles should be accompanied by an abstract of not more than fifty words. Letters should begin with a paragraph giving the background and main conclusions in terms intelligible to as wide a readership as possible.

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the *Système International*. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible; $\exp(a)$ is preferred to e^a if 'a' is more than one character.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) only one reference number need be used if the reference is to several papers by identical authors,

(ii) first and last pages of references should be cited.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed. (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished' should be incorporated in text.

Artwork should be sent with the manuscript and clearly marked with author's name and the figure number. Line drawings should be either photographic prints or in Indian ink on heavy cartridge paper, tracing paper or similar materials. Most figures are reduced to one column width so originals should be about as wide as a page of *Nature*. To enable figures, particularly maps, to be edited in the same style as the text, they should contain only essential material. Ideally, an unlettered original and three lettered copies should be provided; labelling on half-tones should, if possible, be avoided entirely.

Magnifications quoted should be for the figures as submitted. We are always glad to see artwork for possible use on the cover, but cannot guarantee its return.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

Nature's publishing policy is outlined in 258, 1 (1975) and 264, v, 11 Nov. (1976).

Regulation of requirements for anchorage-independent growth of Syrian hamster fibroblasts by somatic mutation	J. C. Leavitt, B. D. Crawford, J. C. Barrett and P. O. P. Ts'o	63

Cover picture

A photograph of the quasi-stellar object 3C 273. One of the nearest and the brightest of the quasars, 3C 273 has a unique jet extending from its otherwise star-like image. Superimposed is a graph of the ultraviolet spectrum of the quasar obtained with a telescope launched aboard a sounding rocket. The strongest emission feature is the Lyman α line of hydrogen. See page 203.

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the *Système International*. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible; $\exp(a)$ is preferred to e^a if 'a' is more than one character.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note: (i) only one reference number need be used if the reference is to several papers by identical authors,

(ii) first and last pages of references should be cited.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed. (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished' should be incorporated in text.

Artwork should be sent with the manuscript and clearly marked with author's name and the figure number. Line drawings should be either photographic prints or in Indian ink on heavy cartridge paper, tracing paper or similar materials. Most figures are reduced to one column width so originals should be about as wide as a page of *Nature*. To enable figures, particularly maps, to be edited in the same style as the text, they should contain only essential material. Ideally, an unlettered original and three lettered copies should be provided; labelling on half-tones should, if possible, be avoided entirely. Magnifications quoted should be for the figures as submitted. We are always glad to see artwork for possible use on the cover, but cannot guarantee its return.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

Nature's publishing policy is outlined in 258, 1 (1975) and 264, v.11 Nov. (1976).

Transcriptional controls and dosage compensation in <i>Drosophila melanogaster</i>	R. L. Roehrdanz and J. C. Lucchesi	243
Endocytosis of red blood cells or haemoglobin by activated macrophages inhibits their tumoricidal effect	J. B. Weinberg and J. B. Hibbs, Jr	245
Inhibition of adipose conversion of 3T3 fibroblasts by tumour promoters	L. Diamond, T. G. O'Brien and G. Rovera	247
Effect of microtubular antagonists on lymphocyte mitogenesis	S. A. Rasmussen and R. P. Davis	249
Immunoglobulin binding to herpes virus-induced Fc receptors inhibits virus growth	J. Costa, A. S. Rabson, C. Yee and T. S. Tralka	251
Excretion of feline leukaemia virus by naturally infected pet cats	D. P. Francis, M. Essex and W. D. Hardy, Jr	252
Blood group-like activity released by human mammary carcinoma cells in culture	J. H. Anglin, Jr, M. P. Lerner and R. E. Nordquist	254
A-specific autoantigenic ovarian glycolipids inducing production of 'natural' anti-A antibody	P. Arend and J. Nijssen	255
Reconstruction of photoreceptor membrane potentials from simultaneous intracellular and extracellular recordings	P. B. Pynsent and G. Duncan	257
Immunological identification of rat neuropsychin precursors	M. J. Brownstein, A. G. Robinson and H. Gainer	259
Several of the adenosine deaminase isozymes are glycoproteins	D. M. Swallow, L. Evans and D. A. Hopkinson	261
Translation of human immunoglobulin heavy chain mRNA <i>in vitro</i>	C. K. Klukas, F. Cramer and H. Gould	262
Identification of chromosomal location of yeast DNA from hybrid plasmid <i>pYeleu 10</i>	J. Hicks and G. R. Fink	265
Deuterium NMR study of lipid organisation in <i>Acholeplasma laidlawii</i> membranes	G. W. Stockton, K. G. Johnson, K. W. Butler, A. P. Tulloch, Y. Boulanger, I. C. P. Smith, J. H. Davis and M. Bloom	267

Mathematical models in applied ecology	G. R. Conway	291
--	--------------	-----

ARTICLES

Ocean-floor magnetotelluric sounding over North Central Pacific	J. H. Filloux	297
Deep-sea carbonate and the deglaciation preservation spike in pteropods and foraminifera	W. H. Berger	301
Structure of a dinucleoside phosphate-drug complex as model for nucleic acid-drug interaction	S. Neidle, A. Achari, G. L. Taylor, H. M. Berman, H. L. Carrell, J. P. Glusker and W. C. Stallings	304
Orientation of cell-surface antigens in the lipid bilayer of lymphocyte plasma membrane	F. S. Walsh and M. J. Crumpton	307

LETTERS TO NATURE

Possible fast variability of the nucleus of Cen A at 13.5 mm	P. Kaufmann, P. M. dos Santos, J. C. Raffaelli and E. Scalise, Jr	311
Pi 1-2 magnetic field pulsations on dayside cleft field lines	R. R. Heacock and R. D. Hunsucker	313
Linear dichroism probes to study internal electric fields	B. Norden	314
Quasi-Fermi level measurement in an illuminated GaP photoelectrolysis cell	W. E. Pinson	316
The first cubane-type fluoro-bridged cluster	J. C. Jansen, H. van Koningsveld and J. Reedijk	318
Hydrothermal manganese in the Galapagos Rift	G. Klinkhammer, M. Bender and R. F. Weiss	319
Solar influence on North Atlantic mean sea level pressure	P. M. Kelly	320
Copper exclusion as a mechanism of heavy metal tolerance in a green alga	P. L. Foster	322
Genetic variation in wild populations of rain-forest trees	Y.-Y. Gan, F. W. Robertson, P. S. Ashton, E. Soepadmo and D. W. Lee	323
Freezing avoidance by deep supercooling in hydrated lettuce seeds	O. Junttila and C. Stushnoff	325
Guard cell malic acid metabolism during stomatal movements	C. M. Willmer and J. C. Rutter	327
Orientation columns in macaque monkey visual cortex demonstrated by the 2-deoxyglucose autoradiographic technique	D. H. Hubel, T. N. Wiesel and M. P. Stryker	328
Instability of the eye in the dark and proprioception	A. Fiorentini and L. Maffei	330

Guide to authors

● Review articles should be aimed at a relatively wide readership. Many reviews are invited, but submitted articles may also be accepted; it is advisable to consult us before writing a review article.

● Articles may be up to 3,000 words long with at most six displayed items (figures and tables); they are reports of major research developments.

● Letters are brief reports of original research of unusual and wide interest, not in general longer than 1,000 words; they have at most three or four displayed items.

● 'Matters Arising' permits short discussion (up to 300 words) of papers that have recently appeared in *Nature*.

Articles should be accompanied by an abstract of not more than fifty words. Letters should begin with a paragraph giving the background and main conclusions in terms intelligible to as wide a readership as possible.

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the *Système International*. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible; $\exp(a)$ is preferred to e^a if 'a' is more than one character.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note: (i) only one reference number need be used if the reference is to several papers by identical authors, (ii) first and last pages of references should be cited.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed. (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished' should be incorporated in text.

Artwork should be sent with the manuscript and clearly marked with author's name and the figure number. Line drawings should be either photographic prints or in Indian ink on heavy cartridge paper, tracing paper or similar materials. Most figures are reduced to one column width so originals should be about as wide as a page of *Nature*. To enable figures, particularly maps, to be edited in the same style as the text, they should contain only essential material. Ideally, an unlettered original and three lettered copies should be provided; labelling on half-tones should, if possible, be avoided entirely.

Magnifications quoted should be for the figures as submitted. We are always glad to see artwork for possible use on the cover, but cannot guarantee its return.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

Nature's publishing policy is outlined in 258, 1 (1975) and 264, v, 11 Nov. (1976).

Leukocytes are consistently associated with degenerating embryos in IUD-bearing rhesus monkeys	P. R. Hurst, K. Jefferies, P. Eckstein, K. Dawson and A. G. Wheeler	331
Active thymus derived suppressor lymphocytes in human cord blood	M. B. A. Oldstone, A. Tishon and L. Moretta	333
Evidence for a common evolutionary origin of gastrin and cholecystokinin	L.-I. Larsson and J. F. Rehfeld	335
Gonadotrophin-releasing hormone deficiency in a mutant mouse with hypogonadism	B. M. Cattanach, C. A. Iddon, H. M. Charlton, S. A. Chiappa and G. Fink	338
Nigral and striatal dopamine release under sensory stimuli	A. Nieoullon, A. Cheramy and J. Glowinski	340
Chlordiazepoxide selectively augments GABA action in spinal cord cell cultures	D. W. Choi, D. H. Farb and G. D. Fischbach	342
Phosphorylation of chloroplast membrane polypeptides	J. Bennett	344
Identification of a transformation-specific antigen induced by an avian sarcoma virus	J. S. Brugge and R. L. Erikson	346
Structures of benzo(a)pyrene-nucleic acid adducts formed in human and bovine bronchial explants	A. M. Jeffrey, I. B. Weinstein, K. W. Jennette, K. Grzeskowiak, K. Nakanishi, R. G. Harvey, H. Autrup and C. Harris	348
Nucleotide sequence of <i>Bombyx mori</i> L. tRNA ₁ ^{Gly}	J. P. Garel and G. Keith	350
Melting fine structure of DNA fragments of known base sequence from Φ X174	A. Wada, H. Tachibana, S. Ueno, Y. Husimi and Y. Machida	352

MATTERS ARISING

Generation length and rates of hominoid molecular evolution	V. M. Sarich and J. E. Cronin	354
Reply	G. J. Todaro and R. E. Benveniste	354
Complementation of immune response genes for (T, G)-A-L	A. J. Munro and M. J. Taussig	355
High explosive analogue of the Tunguska Event	B. W. Augenstein	355
Reply	G. H. S. Jones	355
β -Globin mRNA in Ferrara β^0 -thalassaemia	B. G. Forget and D. G. Hillman	355
Reply	S. Ottolenghi, P. Comi, B. Giglioni, R. Williamson, G. Vullo, L. del Senno and F. Conconi	356

BOOK REVIEWS

Essential Relativity: Special, General and Cosmological (W. Rindler)	Paul Davies	357
Comprehensive Immunology (T. Makinodan, E. Yunis, N. K. Day and R. A. Good, editors)	H. S. Micklem	357

Cover picture

Grazing sheep in Australia. There
 may be more than one stable state in
 the relationship between animals and
 the vegetation they graze on, as well
 as in other ecosystems. R. M. May
 reviews ecosystems with a multiplicity
 of stable states on page 471.

Guide to authors

● Review articles should be aimed at a relatively wide readership. Many reviews are invited, but submitted articles may also be accepted; it is advisable to consult us before writing a review article.

● Articles may be up to 3,000 words long with at most six displayed items (figures and tables); they are reports of major research developments.

● Letters are brief reports of original research of unusual and wide interest, not in general longer than 1,000 words; they have at most three or four displayed items.

● 'Matters Arising' permits short discussion (up to 300 words) of papers that have recently appeared in *Nature*.

Articles should be accompanied by an abstract of not more than fifty words. Letters should begin with a paragraph giving the background and main conclusions in terms intelligible to as wide a readership as possible.

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the *Système International*. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible; $\exp(a)$ is preferred to e^a if 'a' is more than one character.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) only one reference number need be used if the reference is to several papers by identical authors,

(ii) first and last pages of references should be cited.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed. (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished' should be incorporated in text.

Artwork should be sent with the manuscript and clearly marked with author's name and the figure number. Line drawings should be either photographic prints or in Indian ink on heavy cartridge paper, tracing paper or similar materials. Most figures are reduced to one column width so originals should be about as wide as a page of *Nature*. To enable figures, particularly maps, to be edited in the same style as the text, they should contain only essential material. Ideally, an unlettered original and three lettered copies should be provided; labelling on half-tones should, if possible, be avoided entirely. Magnifications quoted should be for the figures as submitted. We are always glad to see artwork for possible use on the cover, but cannot guarantee its return.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

Nature's publishing policy is outlined in 258, 1 (1975) and 264, v, 11 Nov. (1976).

Dopamine agonists induce recovery from surgically-induced septal rage	R. F. Marotta, N. Logan, M. Potegal, M. Glusman and E. L. Gardner	513
Viable chimaeras produced from normal and parthenogenetic mouse embryos	L. C. Stevens, D. S. Varnum and E. M. Eicher	515
Ovarian teratomas in mice are derived from oocytes that have completed the first meiotic division	J. J. Eppig, L. P. Kozak, E. M. Eicher and L. C. Stevens	517

Articles should be accompanied by an abstract of not more than fifty words. Letters should begin with a paragraph giving the background and main conclusions in terms intelligible to as wide a readership as possible.

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the *Système International*. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible; exp (*a*) is preferred to e^a if '*a*' is more than one character.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note: (i) only one reference number need be used if the reference is to several papers by identical authors, (ii) first and last pages of references should be cited.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed. (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished' should be incorporated in text.

Artwork should be sent with the manuscript and clearly marked with author's name and the figure number. Line drawings should be either photographic prints or in Indian ink on heavy cartridge paper, tracing paper or similar materials. Most figures are reduced to one column width so originals should be about as wide as a page of *Nature*. To enable figures, particularly maps, to be edited in the same style as the text, they should contain only essential material. Ideally, an unlettered original and three lettered copies should be provided; labelling on half-tones should, if possible, be avoided entirely.

Magnifications quoted should be for the figures as submitted. We are always glad to see artwork for possible use on the cover, but cannot guarantee its return.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

Nature's publishing policy is outlined in 258, 1 (1975) and 264, v, 11 Nov. (1976).

Inhibition of high-affinity choline transport in peripheral cholinergic endings by presynaptic snake venom neurotoxins	M. J. Dowdall, J. P. Fohlman and D. Eaker	700
High densities of benzodiazepine receptors in human cortical areas	C. Braestrup, R. Albrechtsen and R. F. Squires	702
Altered exploratory behaviour after 6-OHDA lesion to the dorsal noradrenergic bundle	S. T. Mason and H. C. Fibiger	704

Guide to authors

● Review articles should be aimed at a relatively wide readership. Many reviews are invited, but submitted articles may also be accepted; it is advisable to consult us before writing a review article.

● Articles may be up to 3,000 words long with at most six displayed items (figures and tables); they are reports of major research developments.

● Letters are brief reports of original research of unusual and wide interest, not in general longer than 1,000 words; they have at most three or four displayed items.

● 'Matters Arising' permits short discussion (up to 300 words) of papers that have recently appeared in *Nature*.

Articles should be accompanied by an abstract of not more than fifty words. Letters should begin with a paragraph giving the background and main conclusions in terms intelligible to as wide a readership as possible.

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the *Système International*. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible; $\exp(a)$ is preferred to e^a if 'a' is more than one character.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) only one reference number need be used if the reference is to several papers by identical authors,

(ii) first and last pages of references should be cited.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed. (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished' should be incorporated in text.

Artwork should be sent with the manuscript and clearly marked with author's name and the figure number. Line drawings should be either photographic prints or in Indian ink on heavy cartridge paper, tracing paper or similar materials. Most figures are reduced to one column width so originals should be about as wide as a page of *Nature*. To enable figures, particularly maps, to be edited in the same style as the text, they should contain only essential material. Ideally, an unlettered original and three lettered copies should be provided; labelling on half-tones should, if possible, be avoided entirely. Magnifications quoted should be for the figures as submitted. We are always glad to see artwork for possible use on the cover, but cannot guarantee its return.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

Nature's publishing policy is outlined in 258, 1 (1975) and 264, v, 11 Nov. (1976).

How Britain Runs Its Science

A completely revised edition of this highly successful wall-chart (*Nature*, 28 August, 1975), showing the organisations and people running British science, is now available. For details and order form, see page xii.

nature*1 September 1977*

South Africa's nuclear intentions

WORLDWIDE alarm over reports that South Africa is on the verge of joining the nuclear weapons club were temporarily stilled last week when Prime Minister John Vorster privately assured the United States that South Africa is not developing nuclear weapons. The assurance is welcome, indeed, but it would be even more comforting if South Africa were to back up its protestations of innocence by signing the nuclear non-proliferation treaty and by placing its nuclear facilities under international inspection, steps which Mr Vorster's government has consistently refuse to take. The flap over South Africa's intentions does, however, have some positive aspects.

The alarm was first raised on 9 August by the Soviet press agency, Tass, which warned that South Africa was about to explode a nuclear device. A few days later, Tass charged more specifically that plutonium for the country's nuclear weapons would come from two 1,000MW reactors that France recently agreed to supply to South Africa. Since the reactors will not be in operation until 1982, and the agreement requires spent fuel from them to be reprocessed in France with the extracted plutonium remaining in French hands, the Soviet charges were hard to believe. Nevertheless, they prompted the United States, Britain, France and West Germany to take the matter up with Mr Vorster and his government.

The public debate was fuelled further last week when Louis de Guiringaud, France's foreign minister, announced in an interview that France also has new information indicating that South Africa was preparing to test a nuclear device. Dr Guiringaud warned that such a test would have "grave consequences", which would presumably include shelving the sale of the two French reactors and further political and economic reprisals.

Although few details of the basis for de Guiringaud's announcement have been revealed, it is widely believed that the concern was based on evidence of extensive construction work in the Kalahari Desert. The evidence was reportedly obtained by satellite and may have sparked the original Tass pronouncement.

South Africa's response to all of these charges was initially to protest that its nuclear activities are entirely peaceful, a protestation that left room for doubt since it

should be recalled that India's explosion of a nuclear device in 1974 was also labelled as peaceful. At his press conference on 22 August, however, President Carter announced that the United States has been given a more complete assurance that South Africa is not intending to develop nuclear weapons.

Specifically, Carter announced that "in response to our own direct inquiry and that of other nations, South Africa has informed us that they do not have and do not intend to develop nuclear explosive devices for any purpose, either peaceful or as a weapon—that the Kalahari test site, which has been in question, is not designed to test nuclear explosives, and that no nuclear explosive tests will be taken in South Africa, now or in the future". Carter added, however, that the United States would "continue to monitor the situation very closely".

Some comfort should be taken from the fact that as soon as allegations were first raised about South Africa's nuclear intentions, four major western powers moved swiftly to put South Africa on notice that a nuclear explosion would have grave political consequences, and that South Africa would not be allowed to hide behind the pretence that an explosion could be called peaceful. South Africa's unequivocal denial of plans to develop nuclear explosives is a welcome statement.

Nevertheless, until South Africa agrees to submit its nuclear facilities to international inspection, suspicions will linger. It should be noted, for example, that the country has large reserves of uranium and a pilot-scale enrichment plant, perhaps capable of enriching uranium to weapons grade. Experts in the United States have publicly stated that they believe South Africa has the technical ability to produce explosives, given sufficient concentration of funds and manpower on the effort. South Africa has now been put firmly on notice that any such attempt would lead to grave political consequences including possible abrogation of trade and economic agreements, but Carter also noted last week that the United States would "renew our efforts to encourage South Africa to place all their nuclear power production capabilities under international safeguards and inspections". That should be a major political priority. □

Technik: the relevance of a missing concept

M. Fores, of the UK Department of Industry, and I. Rey, previously of the Swedish Ministry of Industry, offer their personal suggestion that the absence of an English word to describe the 'useful arts' of manufacture leads to unnecessary confusion in talking about the world of manufacturing

WRITERS in the English language often use words in such a way that 'science' and 'technology' are considered as key features affecting manufacturing. Sometimes they are even wrapped together and simply known as 'science'. Hilary and Steven Rose, for instance, do this in their book *Science and Society*. Such a usage incorporates a number of errors concerning what was once known as the 'useful arts' of manufacture. To show this, we introduce the word *Technik* which is widely used and understood in Germany. It concerns the functioning of natural and man-made things, including the set of principles according to which artifacts work and the methods used in making them. Most continental European languages include such an idea.

One English language study which erred over the general influence of 'science' in the culture was Bronowski and Mazlish's *The Western Intellectual Tradition* (Penguin). They wrote:

What is needed is that in the general history books the development of science should take its place along with political and economic developments. The steam engine helped to shape the modern world at least as much as Napoleon and Adam Smith, but only rarely do historians admit the fact . . .

Few would dispute that the steam engine has had an important influence on the modern world; but it cannot sensibly be thought of as a 'product of science'.

In Germany, if there are two cultures or sub-areas of the general culture, they are not the science and humanities of the English split. They are *Wissenschaft*, concerned with all knowledge and all the subjects of the classical university, and *Technik*. Normally, however, there are three sub-cultures: *Kunst* 'art', the English 'fine arts' and performing arts; *Wissenschaft*; and *Technik*, widely accepted to be separate from both. *Wissenschaft* means the art of handling knowledge, akin to 'gamesmanship' and seamanship'.

The importance of *Technik* stems from the fact that it has been a prime concern of the species from earliest times. Some of its first products were stones sharpened to kill animals for food, or to ward off dangerous animals. Man became a tool-maker and tool-user through *Technik*.

The history of *Technik* is not, however, the conquest of nature. Problems of *Technik* are not seen in terms of nature but rather of a specific job to be done or an artifact to be made. And more complex contrivances strayed further from the natural state of their component materials. A stick, as a lever, was made of wood, directly from the natural world. But a potter's wheel could be made from various materials, probably in combination. And a governor to control the speed of a rotating machine is a contrivance to control a contrivance. Thus the exponent of *Technik* must be obsessed with the artificial, rather than the natural. If the operations of *Technik* shade into those of either of the other two cultural areas, they shade into *Kunst*, rather than *Wissenschaft*. Metal-working skills are an obvious example of craft skills that have been shared between making the products of fine art and useful artifacts.

The 'applied science' concept is a peg on which some have hung their views about manufacturing. Only in English, of the major European languages, can the concept exist, since only English has a meaning for the word science which only includes knowledge of natural pheno-

mena, or the process by which this knowledge is derived. By use of the 'applied science' phrase, the process of *Technik* is made to seem closer to the natural world than it is in practice.

The applied science concept is misleading for other reasons. It implies that a contrast can exist with pure science. Yet there can never be any body of pure science at all, if the criterion used is lack of utility, or lack of applicability of knowledge. All scientific knowledge is put out freely for verification of falsification—so all can be used freely and with no attribution. The most basic ideas of natural science, such as Newton's laws of motion, turn out to be widely applicable in practice. So the bizarre conclusion must be drawn that the purest of science is more widely applicable in practice than work which is done for particular uses, so-called applied work. Applied science as a sensible near-alternative to *Technik* fails because manufacturing cannot be well characterised as the application of scientific knowledge. Furthermore, studies have shown that the rate of technical progress in manufacturing cannot be equated with the rate of adoption of science.

Continental-style *technologie* invariably means what one would expect from its Greek roots (*techné* means art; *logos* means word or law), so it is not the same as English-language technology. British official statistics show that most technologists are engineers; they are not like other types of '-ologists', students of events. The use of the concept of *Technik* avoids this misunderstanding.

Another difference between perceptions of *Technik* and of technology comes with the idea of utility. Acts of *Technik* are accepted to be pointless if there is no demand, within the existing cost pattern, for the useful artifact being made. There are no imperatives of *Technik* along the lines of technological imperatives of the English-language, whereby critics complain that because something can be made it will be made.

Another feature is that *Technik* does not rule well in an aristocratic or a dictatorial situation, if only because it depends more on detail than on principle. The best conception for a contrivance, or the best design for it, is of no use if the detailed manufacture of component parts is not up to standard. The whole may not be greater than the sum of the parts; but if one of the parts is defective, the whole cannot function.

Continental *Technik* is accepted to be a separate cultural area with codes of behaviour, responses and a dignity of its own. The competent *Techniker* does not feel that he has constantly to look over his shoulder at science or the arts, as the exponent of technology often does. Science and arts do not care much for utility and they have a different grasp of the artificial. *Technik* remains a missing concept in English; its absence is the English speaker's loss. □

Potter's wheel: an example of Technik

The French 'nuclear war'

Les écologistes are gaining a voice in French politics. Alexandre Dorozynski outlines their growth

THE French government is currently faced with a political issue it would doubtless have preferred to keep out of the public forum: that of its "all out" nuclear power development programme and, more particularly, of the fast breeder Super-Phénix reactor at Malville, near Lyon. The issue has become political as the campaign preceding the nationwide legislative elections to be held in March next year has got underway. Polls indicate that the election may well give the Socialist-Communist coalition an edge in the National Assembly, and it now seems likely that the 'nuclear weapon' will be used in the forthcoming 'battle'.

Socialist leader François Mitterand has already suggested that a national referendum be held on the nuclear programme. And a loosely-knit group, termed somewhat vaguely and sometimes disparagingly as *les écologistes*, are beginning to represent a political power to be counted with. Under a programme termed *Écologie '78*, they are to be represented at the municipal elections next year. Seven ecological groups will put forward candidates.

Les écologistes first emerged as a political group in 1974 under the leadership of agronomist René Dumont, who received 1.34% of the votes cast during the presidential election that year. Since then, their numbers have increased rapidly: during the municipal elections earlier this year, they mustered an unexpected 10% of the votes. So far, they have refused to support any of the existing political parties, but if they decide to throw their weight one way or the other, they could well alter the balance between right and left.

But who are *les écologistes*? According to the Ministry of the Environment, created in 1971, there are nearly 15,000 ecological associations in France. They

include such groups as the National Federation for the Protection of Nature, created in 1968, now with a membership of about 100,000; the Association for the Rights of Pedestrians (15,000); the French Association for the Protection of Water (about 1,000); and smaller, regional and special interest groups such as the Friends of the Trees of the Loire (500) and the Committee against Atomic Pollution of La Hague (150). Some of these associations overlap, and total membership is probably no more than two million. The first associations were started with specific, sometimes narrow goals, but interest gradually grew to include more general issues concerning modern life; consumerism, means of production, housing, and so on.

Nuclear power concern

One of the major issues now concerning *les écologistes* is the nuclear power programme and the construction of Super-Phénix, which was the bone of contention of some 50,000 marchers who converged on the farming region of Malville, 40 miles from Lyon and 30 miles from Geneva on Sunday 31 July. They clashed with a few thousand police and a paratrooper unit in what has been called the first battle of the French 'nuclear war'. The battle had its casualties—about 100 wounded and one dead. The dead man, Vital Michalon, was a quiet, young teacher of physics and chemistry (and a reserve officer) whose death has been variously attributed to heart failure, to the explosion of a concussion grenade used by police, or to that of an amateurish explosive device put together by the less peaceful *manifestants*.

The 'march on Malville' might have been dismissed as the kind of incident likely to occur during a hot summer (even though the summer was cool and the marchers were soaked by rain) but public polls, in which Frenchmen participate eagerly, indicate a mounting popular concern which the government cannot dismiss. In 1974, three-quarters of representative samples of Frenchmen were "very much in favour of or rather in favour of" the development of nuclear energy. At the beginning of this year, the percentage in favour had fallen to 50%, while that against had risen from 17% to 41%.

A poll carried out for the weekly news magazine *Le Nouvel Observateur* after the 'march on Malville' showed up the somewhat conflicting views of the French on the nuclear issue. Although nearly 70% considered an

Malville: the first battle

increase in energy consumption to be indispensable to the improvement of their way of life, nearly 50% would be "willing to change their consumption habits and way of life if this could stop the construction of nuclear power plants". A majority (56%) approved of Mitterand's suggestion for a referendum on nuclear power. Of those questioned who identified themselves with the Communist party, 76% approved of the proposed referendum, which Georges Marchais, the Communist leader, has since vigorously condemned.

It now seems impossible to keep the public debate from spreading, and politicians, right and left, may be called upon to take sides. The Ministry of the Environment is bound to go along with the government's pro-nuclear stand, especially as Michel d'Ornano (he is the one who lost the Paris mayoralty to Jacques Chirac), now Minister for Culture and the Environment, used to be, as Minister for Industry, one of the proponents of the "all nuclear" power plan. And the importance of the forthcoming debate has grown in the light of recent talk of a moratorium on the construction of new nuclear power plant in Germany.

So what do the ecologists really want? Few of them will deny that, in view of the poverty of French resources in oil and coal, and the built-in limitations to the development of hydro-electric power, some of France's energy should be nuclear. But most consider the intensive programme unreasonable, and the development of Super-Phénix risky. The government, on the other hand, views nuclear power as a means of stopping the outward flow of currency, and the fast breeder as a major trump to play in case of uranium scarcity in the future (and, also, as a potentially marketable technology).

Michel d'Ornano, environment minister

It is certain that without intensive development of nuclear power, the 'official forecast' of 370×10^9 kWh of electricity by 1985 will not be reached, by far. But is this a forecast or a policy statement? Less than half of 370×10^9 kWh of electricity was produced in 1975, and less than one-tenth of that figure in 1950. Ecologists do not fail to remark that Eurodif, Europe's first uranium enrichment plant, at Tricastin, is itself expected to consume some 30×10^9 kWh a year, which is almost as much as the total electrical energy output in 1950. And they also argue that a less spectacular increase in energy production may not mean, as hawks have hinted, a return to the Middle Ages.

Marching for other issues

But nuclear power is not the 'ecologists' only concern. On 15 August, protesters marched on the Larzac plateau, in the southern part of the Massif Central, against the Army's proposed take-over of more than 10,000 ha of land for training and testing. The expansion was planned in 1970 and would have been completed last year, were it not for the deter-

mined opposition of local farmers, who have succeeded in mustering considerable support. In six years of stubborn but largely peaceful opposition, the farmers have become well organised and have learned many tricks. For example, they published a study of cattle and sheep farming in conjunction with an effective public relations operation which included releasing a flock of sheep under the Eiffel tower in Paris; on another occasion they organised a symbolic harvest for the Third World which opened a debate on malnutrition.

The success of the Larzac farmers, who have joined the loose ranks of *les écologistes*, is measured by the fact that the Army has not been able to acquire half of the land it wanted, and that sheep are still squatting on some of the Army-owned land in virtue of ancient pasture rights. Conscious of public opinion, the Army has seldom resorted to expulsion by force.

Les écologistes have also contributed to the sinking of a proposal to construct a super-highway in Paris (the *Radiale Vercingétorix*, named after the famous Gaul warrior), to preserving some sites from urbanisation, to

promoting legislation against water pollution, to imposing controls on the asbestos industry, and to banning the 2-4-5T defoliant. But it should not be forgotten that they are a variegated group, which includes the scientifically inclined, philosophers, and dreamers who yearn for the unpolluted paths cherished by Jean Jacques Rousseau and probably gone forever.

Many of them, and the public, simply do not recognise the boundary between dream and reality because they are not well enough informed. Most, however, appear to have a genuine concern about the environment as a part of society that has changed irreversibly, and believe, as voiced by Giscard d'Estaing at a ministerial council last July, in "the importance of environmental policy as a factor of transformation of society".

As Frenchmen shift to high gear in their semi-permanent political campaigning, the hope is for a reasonable, informative debate. Perhaps then the traditionally central authority, and the inevitably peripheral, but increasingly concerned, citizen will find a common point. □

USA

New DNA draft

An important new factor has been injected into the long-tangled process of developing legislation to control recombinant DNA research in the United States. Colin Norman reports

WHEN members of Congress left Washington for their summer vacations a month ago, two separate versions of legislation to control recombinant DNA experiments were under consideration. In the Senate, a bill developed by Senator Edward Kennedy's Health Subcommittee was awaiting consideration by the full Senate, while in the House, a bill drafted by Representative Paul Roger's Health Subcommittee was pending before the House Commerce Committee. When Congress returns next week, however, a third version will have to be taken into serious consideration, and the already murky legislative outlook has become even more opaque. In fact, there is now a real possibility that Congress will not complete its work on the legislation this year.

The new version has been drafted by Senator Gaylord Nelson, a Democrat from Wisconsin, in response to concerns which a number of scientists have voiced over the Kennedy bill. Nelson

says he plans to offer his bill as an alternative to Kennedy's when the legislation is brought to a vote in the Senate, and the move will guarantee a full-scale debate on some of the key issues.

The Kennedy bill has aroused some concern because it would establish a Presidentially-appointed commission to draft new rules for recombinant DNA experiments, licence facilities and approved experiments, an arrangement which many scientists view as a recipe for bureaucratic delay. The bill would also establish hefty fines for those who violate the rules and it would allow state and local governments to write regulations which would be stricter than the federal controls. The House version would be less restrictive since it would leave most of the responsibility for implementing controls in the hands of local biohazards committees, and it would also place considerable restraint on the authority of local governments to set their own recombinant DNA regulations.

Until recently, the Kennedy bill was moving through the Senate without encountering much Senatorial interest or opposition, and it was scheduled for a vote in the full Senate shortly before the August recess. It was shunted aside by more pressing legislation, however, and it is still pending. The delay has

enabled a number of scientists to step up their lobbying, and their concerns have met with a sympathetic reception in Nelson's office. Nelson's proposed bill is very similar to the House version, though in some respects it is even less restrictive.

Though Nelson has not actively sought supporters for his bill, his office has been receiving a number of calls from other Senate offices expressing interest. In addition, other Senators, including Moynihan of New York, Eagleton of Missouri and Chafee of Rhode Island, have voiced concern about Kennedy's proposal to establish a new recombinant DNA commission. In short, Nelson's bill is likely to gather considerable support. Nevertheless, if it is put to a vote and it goes down to a heavy defeat, those who support the Kennedy bill would have their hand considerably strengthened when negotiations begin to iron out differences between the House and Senate bills.

Meanwhile, the Roger's bill is not likely to be approved by the Commerce Committee much before the end of September, and it may then be referred to the House Science and Technology Committee. That would delay passage by the House until mid-October at the earliest, which means that there would be little time to reach a compromise with the Senate version before Congress goes into recess before the end of October. □

IN BRIEF

EEC research

The European Commission has recently sent proposals for a new European science and technology policy to the Council of Ministers. In a communication called *The Common Policy in the Field of Science and Technology*, it suggests a new structure for cooperation and some areas where collaborative research should be increased.

Since 1973, energy has taken 64% of the Community R&D budget. The proposals say that this balance should be redressed and suggest that a new programme of forecasting and assessment in science and technology (FAST) be set up. FAST will be a collaborative effort between research groups in Europe and international bodies with an initial budget of 4.4 million ua (1ua=£0.66).

ICRF sues for libel

Lawyers for the UK Imperial Cancer Research Fund (ICRF) have recently issued writs for libel against Daily Mirror Newspapers Ltd. The legal action has arisen over an article published in the *Sunday Mirror* on 14 August, questioning whether some of the £23 million which the ICRF has invested could be put to better use.

The ICRF replied to the article in a statement issued on 15 August which explained that such a high level of investment was necessary to support long term research. The decision to sue for libel was taken after the *Sunday Mirror* refused to publish an apology.

Engineering inquiry

Following hard on the heels of the UK

Department of Education and Science's (DES) discussion paper *Industry, Education and Management is Education, Engineers and Manufacturing Industry*, a report prepared for the British Association for the Advancement of Science (BAAS) under the direction of Dr Joseph Pope, Vice Chancellor of Aston University. Like the DES publication, the BAAS report is the outcome of an investigation into ways of encouraging able professional engineers to enter British industry.

The report puts some of the blame for industry's ills on the low status of engineers, which discourages young people from entering the profession. It recommends that universities and polytechnics accept candidates without 'A' level physics. More women should also enter engineering.

THE principal mountains of California, the Sierra Nevada, run in a north-south chain. They are unbroken by highway crossings for 165 miles of their greatest height. Within this vast area, about 40 miles wide by trails, are two National Parks, Kings Canyon and Sequoia. North of Kings Canyon Park is the equally splendid Sierra National Forest. The flank of the Sierra lying east of the summit crest is outside the park boundaries, and within Inyo National Forest. Much of the terrain outside the parks has been designated as Wilderness Area, administered by the US Department of Agriculture. Happily, there is collaboration between the Departments of the Interior and Agriculture in administering this scenic treasure, which in recent summers has swarmed with knapsackers. In 1976, for example, it received 1.1 million visitor-days of use.

"The Earth was created by the assistance of the Sun, and should be left as it was". So, we are told, said Chief Joseph of the Nez Percé. Much of the Earth is no longer as it was, but Chief Joseph's concept is still the guiding principle for managing wilderness. Detailed instructions of the observation of this principle are given to human invaders at the entry points to the wilderness, which are monitored. Yet there are anomalies. One of them is the presence of saddle horses and pack mules, whose excretory reflexes seem to be stimulated while wading through streams. These animals, however, are allowed to mar the wilderness; they have a strong hold on western American traditions.

Another interesting problem is that pet dogs are permitted in wilderness

areas that lie outside the boundaries of national parks. I have just returned from the John Muir Wilderness Area and its visiting dogs. One of the most prominent breeds was the Labrador retriever, a dog that

Wilderness areas

THOMAS H. JUKES

enjoys jumping in a mountain lake to fetch a piece of wood. The name of the canny Scotsman, Muir, has been given to many other California landmarks, including schools, a hospital, a national monument and a famous trail. Perhaps Muir's wilderness area should be re-named for his dog, 'Stickeen'. An even better idea would be to exclude the dogs, so that native mammals would be less harassed.

A further anomaly: hunting, in season, is permitted in wilderness areas of national forests, but not in national parks. Sharpshooters lie in wait just outside the park boundaries

to pick off deer that heedlessly step outside the demilitarised zone. The official instructions issued to wilderness users remind them, almost plaintively, that target practice with firearms is illegal, but hunting is not.

Our camp was evidently in the territory of a marmot. These beasts usually greet intruding hikers with a shrill whistle, and then scurry into holes. This one walked into camp, apparently to be photographed, after which it fixed us with a withering stare, and refused illegal offerings of food. Another frequent visitor to camps is a raucous bird, Clark's nutcracker. Now I know that the regulations say that the entrails of fish should be carefully buried at least 100 feet from water, but Clark's nutcracker would much rather devour them on the spot, and I could not resist his supplication. Next morning, at daybreak, he awakened me in the whitebark pine just above my head with a loud scream to demand breakfast.

At timberline, about 11,000 feet, the flowers make a mockery of all amateur and professional gardeners. Last week, in Pioneer Basin, it was the time for blue, mauve and pink penstemons: small blue-and-white lupines, golden bush potentillas; rose epilobium, and both large and tiny yellow monkey flowers. Eastern brook trout (*Salvelinus fontinalis*) in the high lakes scorned, for the most part, the offerings of anglers. There were some splendid afternoon thunderstorms, the nights were clear and star-filled, and the mornings blazed with sunlight. In general, the visitors, with their small tents and bright clothing, were heedful of Chief Joseph.

Sinking of 'Cavtat'

SIR,—With regard to the report by Alastair Hay (26 May, page 301), on the sinking of the Yugoslav ship 'Cavtat', off the coast of Otranto in southern Italy, I understand that there is no evidence that poisonous lead derivatives have leaked from the drums in which they are sealed.

The article, however, is decorated with the picture of an Italian fisherman holding fish, with the caption "Poisoned fish caught in the Gulf of Taranto". That picture and caption will certainly capture the attention of most readers of *Nature*, and it will mislead them into thinking that if they visit that area, they will be at high risk of being poisoned. Because this is clearly not the case, the above picture seems ungenerous toward the people of the area, who are heavily dependent on tourism and may suffer from the effect of an unfortunate picture and caption published in an authoritative journal like *Nature*.

Effects of marine research

SIR,—Each time I re-read Desmond Scott's assessment (30 June, page 762) of the effects on marine research of the Third United Nations Conference on the Law of the Sea, I get more annoyed. It is not that his forecast seems improbable—coastal states are indeed likely to exert total control over all scientific research on their continental shelves and within 200 miles of their shores. But the account of how this situation arose and how it should be cured exhibits a curious bias.

Scott appears to attribute all political difficulties between developing and developed countries, especially as they pertain to ocean resources and jurisdiction, to the marine scientists. His view of them is surprisingly bitter and unfortunately misleading. I contend that the scientists had little to do with creating the problem and can do little to solve it. In the confrontation between the developed and developing countries, related as it is to the history of colonialism and its children, post- and neo-colonialism, and accompanied by the emergence of the 'new economic order', marine science has played a pretty trivial role.

The issue of control over marine

science was initially evoked for bargaining purposes, could well have been dropped once the question of jurisdiction over coastal resources was settled, and now refuses to go away, to the great eventual cost of all who use the ocean and its resources or are affected thereby. International interactions under the new law of the sea will be among governments, not individuals, and there are few governments whose actions are determined by scientists, especially when larger political forces are at play.

Harvesting whales

SIR,—In your 'in brief' columns (16 June, page 576) there is a confused and inaccurate account of some analyses I have done on the dynamics of harvested populations. Particularly misleading is a belief attributed to me that certain whale species are under the threat of extinction due to the dynamic instability of the harvesting strategy. I have never made any statement to this effect and do not believe it to be true. Indeed the idea is absurd.

Darwin and his flowers

SIR,—In view of your reviewer's acceptance of "the role of plants in Darwin's scientific life," (21 July, page 273) it may be of interest to mention that in a collection of unpublished letters from eminent botanists and gardeners, written to the late William Robinson, editor of *The Garden* (1871–1927), and preserved by a member of this Association related to Robinson, are some written by Charles Darwin from Downe, Kent in 1875.

On 4 January he wrote: "I am much obliged for your kind gift of six copies of *The Garden*, with a drawing of myself and a notice of my works. This notice is drawn up in the most generous spirit and is highly honourable to me. I thank the writer very sincerely."

In a further letter he wrote: "I may mention (though it is improbable) that you can aid me on one point. If you have some *Euryle ferox*, and if it produces more than one flower at a time, I wish you would cross some and fertilise some others with their

own pollen, in order to see, when their seeds are counted, whether the cross aids at all in increasing their fertility. The *Euryle* is dead at Kew where they would have made the trial on a large scale for me. Professor Carpavy (?) has advanced this plant as a case of self-fertilisation for many generations with unimpaired fertility."

He also asked for some experiments with two distinct plants of *Nymphaea* which were protected while expanded from insects. On 5 May he wrote: "I write . . . to thank you and to say that it will be superfluous to castrate the flowers which are crossed with a pollen from a distinct plant, grown under as different circumstances . . . as maybe. . . . The flowers fertilised with their actually own pollen should certainly be protected from insects. . . . I was glad to see you elected to the Linnean Society."

Charles Darwin's chief contribution seems to have been to make the world realise that plants have a history as well as a structure which had been the sole concern of most botanists.

Grants for social science

SIR,—The article 'Research on research' (4 August, page 398) refers to the sum of £25,000 transferred to the Social Science Research Council (SSRC) from the Council of Scientific Policy (CSP) for science policy studies. You state that the research grant to the Science Policy Research Unit (SPRU) at the University of Sussex "means that other applications are denied". This is untrue, and is a misunderstanding of SSRC's procedures.

The grant made to SPRU is under the SSRC's research grant scheme, and the funds come from the general research grant allocation. The sum transferred to SSRC from CSP for science policy studies is at the disposal of the Research Initiatives Board (RIB) for research contracts. Should the RIB and Council decide to give greater priority to science policy studies it is up to them to take a further initiative in this area.

It is therefore untrue that the research grant to SPRU closes the door to other applicants.

news and views

Nucleosome core structure

from Michael Spencer

THIS issue of *Nature* (page 29) contains the first results of an examination of crystals made from chromatin core particles. The analysis, by Finch *et al.* of the MRC's Cambridge laboratory, is an impressive result of applying all the resources of a multidisciplinary group to rather limited data, so as to extract from it the maximum amount of information.

The core particle is a repeating unit containing 140 base pairs of DNA and an octamer of basic proteins, and is a degradation product of the complete nucleosome which (in rat liver) contains 200 base pairs and an extra protein. Earlier workers on nucleosomes have used electron microscopy, X-ray and neutron diffraction, and biochemical techniques, to build up a tentative picture of a somewhat asymmetrical particle with a hole in the middle, the DNA being wrapped round the outside. A model which anticipated some of the features seen by Finch *et al.* has been described by Richards *et al.* (*Cell Biology, Int. Rep.* 1, 107; 1977). Finch *et al.* have now established a model of this type in a rigorous manner and filled in some new details, by developing a large scale preparation method for homogeneous core particles and obtaining single crystals.

Crystals were first obtained in 1975 by Bakayev *et al.* (*Nucleic Acids Res.* 2, 1401), but they could only record powder diffraction patterns because the crystals were too small. Even now the analysis is restricted to details larger than about 20 Å, either because of the disorder within the crystals or because there is a combination of small crystal size and large unit cell. It is enough, however, to define a probable path for the DNA and to suggest some features of the protein core. An interesting new technique, which will surely be applied

to other large structures in the future, has been the use of electron microscopy to deduce the phases of the X-ray reflections. This vital information, without which a structure cannot be solved, is often deducible only with the aid of isomorphous derivatives which in the present case were not available.

Finch *et al.* got round this difficulty by taking electron micrographs of small fragments of single crystals, and obtaining optical diffraction patterns from the micrographs. Some of these patterns could be identified with the three different X-ray patterns obtained with each of the unit cell faces at right angles to the beam (the 'principal projections'). Having done this, they calculated Fourier transforms from the density distributions in the micrographs and used these to deduce phases (or signs) for most of the X-ray amplitudes. The remaining signs, which were needed to extract the fine detail information present in the X-ray patterns, were deduced by trying different combinations of signs until the three independent particles in the unit cell looked as similar as possible in the calculated electron distribution.

The picture that emerges is of a roughly disk-shaped particle of diameter 110 Å and thickness 57 Å, divided into two symmetrically arranged halves along its short axis and somewhat wedged-shaped, like a half-open oyster. The authors have, with Cantabrigian erudition, coined the name 'platysome' to describe it. The DNA cannot be positively located, but the electron distribution suggests that it forms a superhelix of pitch 28 Å round the outside of the protein core. Now enzyme digestion studies by a number of workers (for example Simpson & Whitlock *Cell* 9, 347; 1976) show that nucleosome DNA chains are most sensitive to attack at intervals of 10 bases along their length. This is consistent with a DNA double helix of 10 base pairs per turn wrapped round a protein core. There are, furthermore,

tracts of relatively low sensitivity which suggest that the protein is in closer contact with DNA at two points in each turn of the superhelix. From this Finch *et al.* deduce that the DNA occupies $1\frac{1}{2}$ turns of superhelix per particle, and that the digestion pattern is consistent with the core possessing a dyad or axis of symmetry.

One further feature of the model is of interest. It has been known for some time that when closed circular DNA interacts with histones to form synthetic nucleosomes, the DNA appears to twist up to form $1\frac{1}{2}$ turns of left-handed superhelix per nucleosome (for example Germond *et al. Proc. natn. Acad. Sci. U.S.A.* 72, 1843; 1975). Since a single turn of superhelix would be too large to account for the known size of a nucleosome, various ingenious schemes have been postulated involving folds or kinks in the DNA to make it more compact. Now, however, Finch *et al.* believe that the DNA is not kinked, but that the Watson-Crick helix winds up slightly on interaction with the histones. (It is not suggested, as eager iconoclasts might conclude from the paper's abstract, that there is any change in the sense of the helix). If the histones were removed the DNA would then unwind from 10 to between 10.4 and 10.7 base pairs per turn. The fact that purified DNA fibres show exactly 10 residues per turn in the B form could arise from a distortion due to crystal packing, and Levitt (one of the paper's authors) has done energy calculations that support this view.

What next? Clearly, there is hope that better crystals will give data at higher resolution. The best crystals obtained so far have, paradoxically, come from particles in which there was considerable protein degradation. This is clearly unsatisfactory, but the authors give reasons for believing that the gross structure is similar to that of intact particles. It does not follow that intact nucleosomes do not have identical structures; little is known about why

homogeneous preparations can still refuse to crystallise, as many workers on tRNA know to their cost. In any case the present work is a promising

start, and we can look forward to following a period of intensified competition between the interested laboratories. □

Can surfaces of metals spontaneously distort?

from John Pendry

THE simplest model of atomic arrangements at clean surfaces assumes that the surface is created by removing all atoms on the vacuum side of the surface plane whilst freezing the positions of those on the crystal side. Such a model belies the complexity of forces at surfaces: structure is determined by the electronic energy levels which are known to be severely distorted by the presence of a surface, and the wonder is that so simple a model should ever work rather than that there are exceptions to it!

Deviations from the model are particularly easy to detect when they involve structure of new symmetries, that is, puckering of the surface. In that instance the diffraction pattern obtained using a beam of low energy electrons changes and acquires extra

details clearly visible on the fluorescent screen used to detect the electrons. It was in this way that two groups (Felter, Barker and Estrup at Brown University (*Phys. Rev. Lett.* **38**, 1138; 1977) Debe and King at Liverpool University, (*J. Phys. C* **10**; 1977)) working independently, discovered a structural rearrangement on the (001) surface of tungsten. A similar rearrangement on the (001) surface of molybdenum was also observed by the Brown group.

The rearrangement occurred below 300 K and the transition appeared to be perfectly reversible. In a subsequent preprint Debe and King report a determination of the space group of the new structure, and are currently analysing intensities in their diffraction pattern in order to find the detailed atomic configuration.

Although observation of a structural rearrangement is relatively simple it is no trivial matter to be sure that it was not induced by impurities. In fact hydrogen is known to induce a similar structure on a tungsten (001) surface. The present structure was probably originally observed by Yonehara and Schmidt (*Surface Sci.* **25**, 238; 1971) but the question of hydrogen contamination could not be resolved at that time. The present work establishes conclusively that the structure is a clean surface effect. The Brown group also demonstrate that it is not due to a phase transition in the bulk of the material; chromium is known to have such a transition, but molybdenum and tungsten were both shown to be free of bulk transitions by X-ray analysis which is sensitive only to bulk effects.

It has been clearly shown that the distortion is due to an intrinsic property of the clean tungsten surface but it has yet to be established which particular property is responsible.

The stable structure of a system is always the one with lowest free energy (E) so that if we plot E as a function of, say, the amplitude (d) of a periodic displacement of the surface atoms it will appear as shown in Fig. 1. Two cases are shown. In Fig. 1a the free energy has two minima which vary as functions of temperature. At the transition temperature the second minimum overtakes the first and the stable structure jumps discontinuously to one with a finite-amplitude periodic displacement of the surface atoms. For the surface to achieve the newly stable configuration many surface atoms must jump across the potential barrier between the metastable and stable structures. It is a characteristic of such transitions that they are 'sluggish' tending to show supercooling and superheating effects.

No such hysteresis was observed in this experiment and it is more likely that the transition was of the so-called 'soft mode' type shown in Fig. 1b. The restoring force for the displacement in this type of transition goes continuously to zero as the temperature is lowered to the transition point. Hence there is a precursor to the transition in the form of a vibrational mode whose frequency goes to zero, that is to say goes 'soft', as the temperature is lowered. Below the transition point the amplitude of the periodic displacement becomes finite, increasing with decreasing temperature. The period of the distortion need not be commensurate with the original lattice spacing but in the instance of the tungsten (001) sur-

Fig. 1 Free energy plotted as a function of d the amplitude of a periodic displacement of surface atoms; a, for the case of two minima; b, for the case when a soft mode appears.

Fig. 2 a, Schematic density of electronic states with a large peak near the Fermi energy which favours a transition that splits the peak as shown in (b), thus lowering the average energy of electrons.

John Pendry is Head of the Theoretical Physics Group at the Daresbury Laboratory.

face it appears to be so, the new periodicity being double the old one.

A common mechanism for producing soft modes is the occurrence of a high density of electronic states near the Fermi level, giving rise to a so-called Peierls instability. The argument is that distortions of lower symmetry split the electronic levels, driving some above and some below the Fermi level. Figure 2 shows the general idea. If the density of states at the Fermi level is high enough the lowering of energy in the occupied states will cancel other positive contributions and make the distortion energetically favourable.

It seems likely that a theory of the clean surface reconstruction will also shed light on chemisorption of foreign atoms. The Brown group observed that adsorption of hydrogen produces diffraction patterns that though different from the reconstructed clean surface pattern, have certain features in common with it. They speculate that hydrogen induces the surface to reconstruct even when the temperature is above the clean surface transition point. If this is correct it is to be expected that the soft mode responsible for the reconstruction will affect the energies of chemisorption.

These experiments challenge our understanding of surface electronic structure and its role in creating soft modes. Densities of states at surfaces are not easy to determine with the precision demanded here, but on the other hand as much experimental information is available about the electronic structure of tungsten as almost any other material and some interesting developments can be expected. □

Disulphide bonds and protein folding

from M. J. Geisow

THE study of the mechanisms by which proteins fold seeks to unravel the stereochemical determinants of tertiary structure, with the commendable long-term goal of predicting three-dimensional structure from amino acid sequence. Advances in the 1970s, both in formulations of concepts and in theoretical and experimental treatments of protein folding have been comparable with the rapid development of protein crystallography in the 1960s. By analogy, the next decade should see the first predicted structures, a preview of which might be the successful approximation of the pancreatic tryp-

M. J. Geisow is a member of the scientific staff at the National Institute for Medical Research, London.

Globin hnRNA = pre-mRNA

from Bob Williamson

DEFINITIVE work proving the existence of a high molecular weight precursor of mRNA has at last appeared, confirming the suspicions of a decade. Readers of these columns will know that for years the argument has proceeded between those who thought each high molecular weight RNA molecule an aggregate, and those who thought each cleavage due to inadequate purification techniques and omnipresent and omnipotent ribonucleases. Recently several groups, and in particular P. Curtis and C. Weissmann in Zurich, have shown a 15S precursor double the size of globin mRNA in induced mouse Friend erythroleukaemia cells, but this does not satisfy the true exponent of precursors. We need hnRNA molecules 10 times larger than the final product, for a given mRNA, to fit our favoured theory.

Bastos and Aviv have now provided the data (*Cell* 11, 641; 1977). They have looked at nuclear RNA from both mouse Friend cells and mouse spleen, and have found a nuclear RNA containing globin sequences at least 27S in size (approximately 5,000 nucleotides long), or seven times the mRNA length. Aviv's group identified this RNA species using a column of globin complementary DNA (cDNA) bound to cellulose. Since the cDNA was present in large excess the kinetics of hybridisation were favourable even for the small amounts of globin-specific hnRNA present.

After a 5 min pulse of labelled uridine, over two-thirds of the counts are in an RNA molecule sedimenting at 27S. It is processed with a half life of 5 min, first to an RNA of size 15S, previously shown by others, and then to the final mRNA. (There may be a small pool of mRNA in the nucleus,

which takes time to equilibrate to the cytoplasm; there is room in Aviv's data for yet another control step at this point). The scheme seems very similar for Friend erythroleukaemia cells and normal spleen, which is gratifying, since there is always residual concern when a generalisation is based on as atypical a model as a cell in continuous culture transformed by an RNA tumour virus and induced into erythropoiesis by an organic chemical acting on membranes.

The other interesting result presented is that the large 27S precursor has no poly(A) tail; this only appears after cleavage to the 15S molecule. Therefore poly(A) addition is not only a post-transcriptional event; it also occurs as part of intermediate processing. It should be possible shortly to determine whether the poly(A) is added internally and what is the position of the mRNA sequence in the 27S precursor.

Another group has also studied mouse spleen cells in culture using DNA bound to cellulose, and using very rigorous denaturation conditions with treatment by formaldehyde, which breaks secondary structure irreversibly (Kwan, Wood & Lingrel *Proc. natn. Acad. Sci. U.S.A.* 74, 178; 1977). In this case the RNA, pulse labelled for 10 min and prepared by several different techniques, was isolated and run on gels, and showed the 15S precursor peak but no 27S RNA species. The reason why some groups fail to find this larger species while others do is unclear, but may be related to the very rapid processing of nuclear RNA, even while it is synthesised, in some culture conditions.

sin inhibitor structure by Levitt and Warshel (*Nature* 253, 594; 1975).

Many reports of the change of protein structure consequent upon denaturation and refolding have been based on kinetic measurements using optical, chiroptical or magnetic resonance properties of the amino acids to monitor the microenvironment. Typically, these experiments indicate biphasic or multiphasic pathways, which point to the existence of significant intermediate states. Thermodynamic observations are often more simply explained by an equilibrium of native and unfolded forms, suggesting

cooperativity in protein folding. Such a hypothesis is almost certainly an oversimplification for whole proteins, but might well describe the formation of component elements of secondary structure such as β -pleated sheet. The pattern of formation of hydrogen bonds in this structure would seem to provide an excellent physical model for a highly cooperative folding process.

The classical method of studying mechanism in chemistry is to trap intermediate states and infer the pathway from the structures of these intermediates. In disulphide proteins nature has provided just such potential inter-

mediates, since the order of formation of disulphide bridges must reflect the folding pathway. 'Freezing' the reaction by acid or alkylating reagents then provides covalent intermediates for study at leisure.

A prerequisite for the extrapolation of results from the particular disulphide proteins studied to general notions of folding, must be the demonstration that disulphide formation does not provide of itself the dominant driving force for protein folding. The consensus is that the peptide chain promotes rapid and specific disulphide formation and not *vice versa*. For example, in denaturants such as guanidinium chloride, correct disulphide bridging does not occur, even in the presence of thiols to allow disulphide exchange to correct 'wrong' bridges.

Having said this, it is also certain that in the absence of denaturants, the initial disulphide bridges formed are not necessarily native. Workers usually refold proteins in the presence of redox systems such as dissolved O_2 , oxidised and reduced glutathione or even disulphide exchange proteins (reshuffleases) to prevent the accumulation of non-native forms. In all of these oxidation methods it is clear that thiol-disulphide exchange is the principal process which leads ultimately to the native forms. Since a third factor (an oxidised thiol) must participate in the formation of each disulphide bond a question of accessibility arises, particularly for disulphide bridges which are deeply buried in the final structure. The degree to which the oxidative mechanisms influence the folding pathways is not known, but many workers have nevertheless found it relevant to ask what light disulphide bridges can shed upon the folding process.

The questions then are: which are the initial disulphides, what regions of tertiary structure do they connect and are there early native disulphides or do they consist of predominantly non-native forms? The principal answers to these questions have been sought in studies of ribonuclease A (RNase A), bovine pancreatic trypsin inhibitor (BPTI) and lysozyme. These are arguably an unrepresentative group because they are all very small and stable proteins, but they are sufficiently well characterised for precise study.

Two general mechanisms have emerged. The first is a random search mechanism in which a rapid phase occurs where there is formation of many randomly-paired disulphides and mixed disulphides, followed by a reshuffle to the native form. This folding pattern was deduced for RNase A (Hantgan *et al.* *Biochemistry* **13**, 3421; 1974).

The second is a limited search mech-

anism where there is rapid formation of a few specific disulphides, followed by slower reoxidation and exchange of the remainder to produce the native structure. Anderson and Wetlaufer (*J. biol. Chem.* **251**, 3147; 1976) found that the first two native disulphides of reduced lysozyme formed eight times more rapidly than the second two, implying an ordered progression to the final structure. Creighton (*J. molec. Biol.* **95**, 167; 1975) observed that the refolding of BPTI could only take place through the formation of two of the four major disulphide intermediates present initially, suggesting an obligatory folding pathway.

The latter mechanism is certainly more consistent with the idea of nucleation regions which, formed early during folding, predispose to particular disulphide bonds. Creighton notes that the predominant cysteine residues involved in early disulphides in BPTI are at the centre of an α -helix and an antiparallel β -pleated sheet respectively; secondary structure is the favoured site of nucleation in folding proteins. Even if each of these mechanisms is correct for the respective protein, the experiments rule out the 'all or none' or co-operative picture of protein folding, since disulphide formation is far more rapid than the return of biological activity.

More recently an ingenious thermodynamic approach has overcome the technical problems of 'trapping' the rapidly reoxidising disulphide bridges. Acharya and Taniuchi (*Proc. natn. Acad. Sci. U.S.A.* **74**, 2362; 1977) have allowed randomly alkylated lysozyme containing one blocked cysteine residue per mol of protein to refold over an extended period. Enzymically active material isolated after refolding contained eight isomers representing each of the four possible ways of forming three native and one open disulphide bridges. There were similar amounts of these four forms. Such an observation clearly rules out an obligatory pathway for the formation of correct disulphide bonds, since the folding routes must have been independent of each disulphide in turn, although ultimately producing near-native molecules. Acharya's and Taniuchi's result does not fix the sequence of events leading to the correct structure and therefore cannot rigorously distinguish between a random or nucleation folding mechanism. However, the inability of a particular disulphide to form did not appear to influence the final fold. This lends some support to the notion that the early folding events reflect what the peptide chain is trying to do, rather than simply the need of the cysteines for oxidation. The truth, of course, is probably a bit of both.

The recent topological analysis of protein structure by Levitt and Chothia (*Nature* **261**, 552; 1976) points to the presence of a limited set of folding units in globular proteins, composed of adjacent elements of α -helix and β -structure. The elements of secondary structure concerned are also close in linear sequence, suggesting that they could quickly form appropriate interactions to produce units of tertiary structure. Such folding units apparently occur with a statistically very significant frequency in the 31 proteins examined. The authors argue that the folding of proteins is kinetically determined by the high probability of formation of these folding units, which subsequently interact with each other to produce the native structures. This attractive hypothesis might be testable in disulphide proteins. The identification of cysteine residues which would be brought into proximity within a Levitt-Chothia folding unit should coincide with the experimentally observed early disulphides, even though these might not be the final native ones. □

Weather on Neptune

from Garry E. Hunt

STUDIES of the weather systems of planetary atmospheres provide a greater insight into the meteorological processes involved in a wider range of conditions than can be achieved through investigating the Earth alone. In addition to the direct spacecraft observations, Earth-based measurements of the changing cloud patterns of Venus, Mars, Jupiter and Saturn have provided a wealth of data on their atmospheric phenomena. The same approach cannot be applied to atmospheric studies of Uranus and Neptune since these planets are too distant for direct telescope observations of any cloud systems to be possible. In these conditions it is necessary to adopt a subjective approach such as monitoring the planetary brightness spectrum or changes in the absorption spectra formed in the cloudy planetary atmosphere. Certainly patrols of the hydrogen features in the Jovian atmosphere have been shown by Hunt and Bergstralh (*Icarus* **30**, 511; 1977) to be good identifiers of planetary motions and variabilities in the cloud layers. A patrol of the Neptune reflectance by Joyce *et al.* (*Astrophys. J.* **214**, 657; 1977) indicates a substantial but unexpected increase in the planet's reflectance between 1 and 4 μ m, between April 1975 and March

Garry Hunt is in the Department of Physics at University College, London.

1976, with an increase of a factor of 4 at $3.5\ \mu\text{m}$ (L band). Pilcher (*Astrophys. J.* **214**, 663; 1977) suggests that these measurements are the first direct evidence of weather on Neptune caused by rapid variations in the cloud structure. Paradoxically, the simultaneous observations of the nearer planet Uranus show no variation during this observational period. Could Neptune have weather and Uranus not?

The radiative time constant is the time taken for a mass of air to warm up or cool by radiating in the infrared portion of the spectrum. Stone (*Space Sci. Rev.* **14**, 444; 1973) suggests that for Uranus this parameter is about 600 Earth years which is long compared with both its orbital and rotational periods of 84 yr and 22 ± 2 h. Similarly for Neptune the relaxation time is about 2,200 yr which is again enormously long compared with the orbital periods of 164 yr and 21 ± 2 h respectively. Consequently, this would suggest minimal diurnal and seasonal changes in the atmospheric structure of the visible cloud layers. Furthermore, we would expect the planets to behave in a similar manner, which, at first sight, is not borne out by the measurements of Joyce *et al.* (*op cit.*). Is it possible for Neptune to possess a more active weather system or more variable cloud layers?

The increase in the Neptune reflectance observed by Joyce *et al.* must be due to a corresponding increase in the planetary albedo. Correspondingly, it would also require a reduction in the atmospheric absorption, which is substantiated by the smaller amounts of methane and hydrogen they derive, compared with the previous studies by Owen (*Icarus* **6**, 108; 1967) and Encenaz *et al.* (in *Exploration of the Planetary System* ed. Woszczyk, A. & Iwaniszewska, C., Reidel, 1974) respectively. Does this imply a variable cloud structure affecting the level where the absorption lines are formed?

There seems little doubt that the Neptune atmosphere (and Uranus too) will possess layers of cloud. Prinn and Lewis (*Astrophys. J.* **179**, 333; 1973) predict a layer of methane haze in the upper troposphere of both these planetary atmospheres, which may be more substantial in thickness in the colder Neptune environment. At the lower levels, layers of NH_3 , NH_4SH and aqueous NH_3 could possibly form but they are unlikely to affect the spectroscopic or photometric observations. What could cause the methane cloud opacity to vary, since this is the most likely candidate to explain the paradoxical observations of Joyce *et al.*?

Morrison and Cruikshank (*Astrophys. J.* **179**, 329; 1973) found that at $20\ \mu\text{m}$ Neptune has a higher brightness

temperature ($\sim 58\ \text{K}$) than Uranus ($\sim 53\ \text{K}$). Does this mean that Neptune (and not Uranus) may have an internal heat source? It would then be possible for this energy source to produce convective activity in the Neptune atmosphere which would be important in the planet's meteorology. The solar energy at the distance of Neptune is extremely weak, and would therefore have a limited effect in suppressing the atmospheric convection, as is apparently achieved in the region of Jupiter bounded by $+45^\circ$ latitude (Ingersoll *Space Sci. Rev.* **18**, 603; 1976; Hunt *Adv. Physics* **25**, 455; 1976). It would then be possible for this redistribution of atmospheric heating to modify the upper troposphere thereby affecting the condensation processes. The resulting variability in the cloud structure would then create the changes in reflection and absorption properties observed. However, these measurements are for the whole planetary disk, so that it is possible that global scale features are being observed. Perhaps this then suggests that Neptune may not possess belts and zones which are so familiar on Jupiter and Saturn.

But why should Uranus not show similar variations during this time period? The $20\ \mu\text{m}$ observations of Morrison and Cruikshank (*op cit.*) could be interpreted as suggesting that Uranus may not have an internal heat source. This would then imply less convective activity in the Uranus atmosphere, so that perhaps one would not expect to observe variability in the cloud layers. But perhaps Uranus does have an internal heat source. Then it is quite likely for the atmosphere to exhibit some variability, but the time scale may be affected by peculiar inclination of the rotational axis. The level of activity may depend upon the portion of the disk that is observed, so that it is essential for a patrol of the Uranus atmospheric features to be carried out during the next few years.

The brightness of the outer planets, Uranus and Neptune have been patrolled by Lockwood (*Science* **190**, 560; 1975) to study possible variations in the solar constant, which would obviously affect every planetary atmosphere. If these planets, Uranus and Neptune, possess variable cloud layers, which could modify the planetary brightness, then it may be necessary to reconsider this type of study. However, there is little doubt that future studies of the meteorology of Neptune provide a further environment to study atmospheric processes very different from those of the Earth's atmosphere, so that there is a great deal to be done with our telescopes and computers before the planet is visited by Voyager in 1989. □

Structural gene for myosin

from Carol K. Klukas

In a recent issue of the *Journal of Molecular Biology* (**114**, 133; 1977) A. R. MacLeod, R. H. Waterston, R. M. Fishpool and S. Brenner report their identification of a structural gene for a myosin heavy chain in *Caenorhabditis elegans*, a small nematode worm. Their report represents another step in the long term project being undertaken in Sydney Brenner's laboratory to dissect the genetic specification of this creature, a representative and yet manageable eukaryotic organism.

The basic approach is that used to dissect the much simpler genetics of bacteria. In bacteria genetic analysis of mutants provides an outline of the genetic organisation: how many genes are involved in any particular process and how they are arranged on the chromosome for example. Biochemical measurements (such as assays for activity of specific enzymes in various mutants) then can provide information on precisely how the genes work together to specify a particular biosynthetic process within the bacterial cell.

But the problem of deciphering and dissecting the genetic system which dictates the complexities of a multicellular organism, in which different cells each with their particular biochemical processes, must be positioned in a correct spatial relationship and must function in a correct relationship temporally, seem daunting. However, the 1-mm long *C. elegans*, which consists of a total of only some 600 cells and has a life cycle of only $3\frac{1}{2}$ days is an organism uniquely suited to such an attempt.

The DNA content of this worm's genome is only 20 times that of *Escherichia coli*, and of this DNA only 6.7×10^7 base pairs code for unique sequences, enough to code for about 6.7×10^4 average-sized genes. This number is large enough, but is considerably more manageable than that of most other eukaryotes. Furthermore, because *C. elegans* is hermaphrodite, recessive mutants are easy to isolate and since the defect is reliably transmitted to the offspring a ready supply of recessive mutants for study is assured. Although *C. elegans* does not have many external features in which abnormalities can be detected, useful behavioural mutants can be quite easily detected visually whose

Carol Klukas is in the Department of Biophysics at King's College, London.

abnormalities often directly indicate mutations in the nervous system or musculature.

With these advantages in mind, Brenner's group has set about the slow task of dissecting the genetic specification of *C. elegans*, especially that of the nervous system. The work involves the characterisation of mutants such as E675 which maps in the *unc-54* gene and was used in the recent *J. molec. Biol.* paper to identify the *unc-54* gene as the structural gene for a myosin heavy chain present in a major fraction of the total nematode myosin. All worms with mutations in the *unc-54* gene, including deletion mutants, have disorganised muscles due to a drastic decrease in the number of thick filaments in the body wall musculature, but these mutants survive because the pharyngeal muscle continues to function normally. In E675 the myosin has a molecular weight of 2×10^5 rather than the normal 2.1×10^5 component. By means of cyanilation and cyanogen bromide cleavage the authors show that the mutant heavy chain is an altered form of the wild-type myosin

and thus conclude that *unc-54* is the structural gene for this heavy chain.

There are always some thick filaments visible in the body wall cells of *unc-54* mutants, even in the deletion mutants. This indicates the presence of multiple myosins in *C. elegans* as has been noted in higher organisms. In normal worms do other myosins associate with *unc-54* heavy chain to form hybrid myosin molecules or do thick filaments containing mixed myosin populations occur? The suggestion from observation of mutants is that mutant heavy chains can interfere with the production of normal myosin in some way and it will be part of the *C. elegans* puzzle to work out this interplay between myosins and the genes which direct their synthesis.

The whole puzzle is very complex indeed, but each piece which is fitted in by Sydney Brenner's group brings closer a complete picture of just how the information specifying a higher organism is stored in its genes and unravelled in the correct sequence to dictate the development of an organism such as *C. elegans*. □

plate carrying the South Asian sub-continent moved northward and collided with the front edge of the Eurasian plate. It obliquely compressed and in stages ploughed into the ancient Asiatic continent, and in fact is still moving at a velocity of $\sim 0.5 \text{ cm yr}^{-1}$. Palaeomagnetic measurements suggest that the suture of the two plates is located roughly along the Yalu-Tsauo valley.

Gravity and earthquake data suggest that the thickness of the Earth's crust at Mt Jolmolungma (Mt Everest) is $\sim 48 \text{ km}$, much less than that in the vicinity of Lhasa which is $\sim 70 \text{ km}$. Geophysicists found, on the other hand, intense hydrothermal activity along a belt south of the Gangdise Range and north of the Himalayas. The initial interpretation is that this widespread geothermicity is the result of lava activities.

Data were collected along built and planned highway routes, on the occurrence and development of mud-and-stone flows. Glaciation was studied over large areas. Chinese glaciologists are now working out laws of motion pertaining to a rare oceanic (warm) type of glacier, the distinguishing features between this type and the continental (cold) type, and the changing distributions of both on the Plateau. Wave-like glacial movements were also observed for the first time. After long years of slow movement, some glaciers show a sudden burst of speed in their advance. The momentum change is frequently so large that the middle moraines on the surface of the ice are twisted and the ice surface shows cracks like a spider's web.

It is reported that the large quantity of good data are subjecting to severe tests many views currently adopted in the West. For instance, one hypothesis maintains that the Plateau was totally glaciated during the Quaternary Period and that few plants and animals escaped extinction to survive today. The survey, however, indicates that the Tibetan flora and fauna consists of many species, some of which are left over from the Tertiary Period. Tibet has more than 4,000 species of higher plant. Geological data show that during the glacial period in the Quaternary, the glaciers were indeed much larger than at present. At that time the Himalayas could not yet completely block winds coming from the Indian Ocean, and precipitation in most parts of Tibet was greater. However, data indicate that the Tibet Plateau has never been completely covered by glaciers. Another common belief in the West is that northern Tibet is in a drought belt. The survey establishes that the vegetative cover there is basically the grassland type

Surveying the roof of the world

from T. B. Tang

MANY large-scale geographical and scientific surveys have been conducted in China since 1949, particularly in the past five years. In 1973–75, for example, the State Department of Agriculture and Forestry undertook a land resources survey of the Heilungkiang (Amur) region, in which scientists cooperated with the ordinary citizen. The Department of Geology carried out in 1974–77 an airborne geophysical survey of the southern Yellow Sea, East China Sea, and South China Sea. The largest and most comprehensive survey to date must be, however, the four-year expedition to the Chinghai-Tibet Plateau, organised by the Academia Sinica and started in 1973. The Plateau, sometimes referred to as the 'third Polar Region' or the 'roof of the world', is of immense scientific and other interest. In 1951 and 1960, local and specialised surveys were carried out in that vast area, and their results were used in the planning of the present expedition. More than 400 scientists, from 45 institutes and specialising in some 50 disciplines, took part at one time or another. The field work now completed, the programme is entering the stage of laboratory analysis, data processing, synthesis of

results, and theoretical interpretation. In June the Academia Sinica arranged a conference at which selected fossils, photographs and films were shown, and papers describing preliminary results were discussed (*Hsinhua News Agency* and *Ta-kung-pao*).

It has long been known that the Plateau used to be under sea-level, but little was ascertained as to exactly when and how the uplift occurred. That during the early and middle Jurassic period Tibet was a shallow sea or depression was confirmed by the present survey from palaeontological evidence. More than 6,000 fossils have been collected, dating from the Proterozoic and Cambrian periods onwards, and including those of a Hipparion (exhibited at the conference) and a sauropod dinosaur. It is the first time that dinosaur fossils have been found at places now at such a high altitude. (A preliminary regional stratigraphical map has been published.)

In the Pliocene Tibet became low-lying dry land with subtropical conditions. Then, in the ensuing period of several million years, a tremendous uplift took place. The geophysical model most discussed at the conference proposes that the upheaval was generated mainly by the spreading of the Indian Ocean floor, so that the

which is, or can be made to be, good grazing.

Water resources have also been investigated. The survey determines that Tibet has 1,000 lakes, about half of the total in China. Most are tectonic lakes, the rest mainly formed by glaciation. They contain abundant deposits of salt, soda, sodium sulphate, and borax. The lakes have significant effects on the local climates and the areas around them possess great potential for agriculture and animal husbandry. The fish in them are chiefly Schizothoracinae of the Cyprinoid family and barry loaches of the Cobitidae. They are different from those on the plains, preserving many of their primitive features. It is thought that they have evolved from those existing in the late Tertiary Period, and have undergone some adaptive changes during the uplift of the Plateau.

The Chinese collected over 50,000 specimens of higher plants, and over 70,000 of insects, birds, animals, fish and other aquatic life. Preliminary identification work has revealed more than 100 new species of plants, some presumably having developed from known species (during the upheaval)

and some being entirely unique to the Plateau. Identification of the detailed natural-geographic zones is now at an advanced stage. Incidentally, as a result partly of the survey but mainly of research started in 1971 by the Chinghai Institute of Biology, a Tibetan medical pharmacopeia was published in July. It is in three volumes, the first two dealing with herbal drugs and the third with animal products having therapeutic applications. 455 drugs are listed, an outstanding example among which is saussura, a herb with a white pappus, of great medicinal value, but scarce in other parts of China.

Besides providing a wealth of unique scientific data, the survey has located many important mineral, water, geothermal energy, and other resources, and showed that the Plateau possesses agricultural and cattle-raising potential. No doubt the development of Tibet will continue at an ever increasing pace. An oil pipeline is already in existence from Golmo in Chinghai to Lhasa, and work has started on a 2,100-km railway line to link up with the national network.

pointed out by R. C. Staples (Boyce Thompson Institute) in his introductory talk, this approach has led to the poorest farmers often benefiting least from the 'Green Revolution'. Following up this point, F. N. Ponnamperna (IRRI, Philippines) emphasised the tremendous potential for increasing food production without requiring large increases in inputs which is offered by the breeding of new varieties tolerant of stress. He gave examples of the recent advances achieved by the International Rice Research Institute in breeding lines tolerant of soil conditions such as salinity, alkalinity and zinc deficiency.

The conference was significant in that it was probably the first major attempt to review progress in the application of fundamental plant physiological research to the breeding of crop varieties adapted to a range of stressful environments. Although a wide range of stresses including disease, aluminium toxicity and air pollution was covered in the meeting, the majority of papers were concerned with temperature or drought.

Among several interesting contributions was one by M. J. Jaffe (Ohio University, Athens, Ohio) on a commonly neglected stress. He reported a series of studies on the effect of mechanical stimulation, such as might be experienced by plants brushing against one another in the wind, on plant growth and development. Even slight rubbing of expanding internodes was shown to reduce their extension dramatically. G. F. Somers (University of Delaware, Newark) described some speculative work where irrigation with sea water is being used in a programme designed to select new salt-tolerant crops from among wild species native to salt marshes. If successful, this approach alone could greatly increase the world's arable area, since there are large areas with saline soils or where saline irrigation water only is available.

The general problems of improving crop tolerance of stress were illustrated by the contributions in the field of drought resistance. These ranged from reports of fundamental studies at the molecular level to reports by plant breeders actually concerned with breeding new varieties. The present state of the art in breeding for drought resistance in wheat was outlined by F. T. Townley-Smith and E. A. Hurd (Agriculture Canada, Saskatchewan), who described the techniques adopted in their own programme. Although they make some selections on the basis of 'physiological characters' such as the rate of wilting of cut leaves or the length of roots in seedlings, their programme relies heavily on yield measurement as the main selection criterion. Physiologically based screen-

Stress physiology of crop plants

from Hamlyn G. Jones

An international conference on Stress Physiology of Crop Plants sponsored by the Boyce Thompson Institute for Plant Research and the Rockefeller Foundation was held at the Boyce Thompson Institute, Yonkers, New York, on 28-30 June, 1977. The conference was organised by H. Mussell and R. C. Staples.

It is the tropical countries which have the greatest potential for providing the extra food which will be necessary to feed the growing world population, since they have extensive areas of potentially cultivable land where crops either are not grown at all or only yield poorly because of stresses such as drought, non-ideal temperatures or adverse soil conditions. This was the message in the first paper of the conference, given by M. N. Christiansen (USDA, Beltsville).

In the past, much of the effort towards improving crop yields in these situations has involved the breeding of high yielding varieties suitable only for near optimal conditions, with the consequent need to ameliorate the stresses by installation of expensive irrigation systems or by using high inputs of fertiliser or pesticide. As was

Hamlyn G. Jones is a Lecturer in Botany at the University of Glasgow.

A hundred years ago

With reference to Galileo's claim to be the inventor of the telescope, M. Wolf quotes (*Annalen der Physik und Chemie*) from a manuscript of Scheiner (1616) in a library in Zurich, a curious passage, of which the following is part: "It must be allowed first, considering what the telescope does, that Baptista Porta has better right to be thought the inventor, because he describes, after his own way, in obscure words and puzzling expressions, an instrument like the telescope. But secondly, if we speak of the telescope, as it is now used after general perfection, we must say that neither Porta nor Galileo is the first discoverer of it, but the telescope in this sense was discovered in Germany, among the Belgians, and that accidentally by one Krämer, who sold spectacles, and either for amusement, or experimentation, combined concave and convex glasses, so that with both glasses he could see a quite small and distant object large and near; at which success being rejoiced, he united several similar pairs of glasses in a tube, and offered the combination at a high price to wealthy people. Thereafter they (the telescopes) became gradually more common among the people, and spread to other countries. In this way two of them were brought for the first time by a Belgian merchant to Italy.

from *Nature* 16, 30 August, 390; 1877.

ing is not emphasised in their programme, partly because the tests tend to be too complex to use on large numbers of lines and partly because most such tests tend to be poorly related to field performance. This paper highlighted the somewhat depressing fact that, to date, the physiological approach has not made much contribution to the development of new stress-tolerant varieties. In spite of this there was general agreement that really large and rapid improvements in stress tolerance will only come about by cooperation between breeders and physiologists.

- Part of the difficulty is that in the past many laboratory physiologists have been reluctant to face the complexities of the field situation, which is, after all, where their ideas must ultimately be tested. An encouraging feature of the conference was the surprisingly large number of contributions from workers who have been facing this challenge and have begun to study stress physiology in the field and to apply this work to plant breeding. N. C. Turner (CSIRO, Canberra), for instance, reviewed recent work on the mechanisms whereby plants adapt to drought stress in the field. The important message was that the responses observed in the field were frequently quite different from those found in controlled environments so that much laboratory work may be misleading.

It was apparent from the various papers and discussions during the meeting that we are further advanced in our understanding of and ability to breed for tolerance of some stresses such as cold, specific ion toxicities or more particularly disease, than we are for drought. This may be largely a function of the complexity and variability of droughts and the range of possible tolerance mechanisms. Surprisingly, perhaps, those such as A. Blum (Volcani Institute, Bet Dagan, Israel) and C. Y. Sullivan (USDA, Lincoln, Nebraska) who work in the most arid regions, tended to be the most optimistic and appeared to have made most progress in developing physiologically-based screening tests for drought resistance. Sullivan, for instance, reported good correlations between field performance of sorghum and several physiological tests including the ability of disks of leaf tissue to withstand osmotic stress or short periods at high temperatures.

The basic optimism and philosophy both of the conference organisers and of the vast majority of participants is probably best summed up by this extract from the 1976 annual report of the Boyce Thompson Institute: 'We believe that there is no more important task for research to undertake than

providing the technology to feed (and clothe) the continually expanding world population, . . . and that understanding plants and pests at the basic physiological and biochemical level is essential for the future breakthroughs necessary. . . .'

Earthquake prediction

from R. P. Adams

Discussions on earthquake prediction remain one of the drawcards at seismological meetings. It was appropriate that on 16 August a full-day symposium was devoted to this topic at the General Assembly of the International Association of Seismology and Physics of the Earth's Interior, being held at Durham.

INTERNATIONAL interest was evidenced by the fact that authors from seven different countries contributed the fifteen formal papers. It was fitting that three papers were given by scientists from the People's Republic of China, as this was their first chance to appear at meetings sponsored by the International Union of Geodesy and Geophysics since China's admission to that body 10 days earlier.

In coming from the only country yet to have successfully predicted major earthquakes, the Chinese have a clear lead in this field. Their first paper, presented by Chang Yu-ming on behalf of a group of 10 authors, discussed in detail the general seismotectonics of China, while two later papers dealt with detailed descriptions of precursory phenomena associated with known earthquakes. Tung Sung-sheng spoke of variations in seismic velocity in Yunnan Province that enabled a general warning to be issued a year before two earthquakes of magnitude 6.7 and 6.4. Chen Yun-tai reported observed changes in gravity measurements of up to 350 μ gal before and after the successfully predicted Haicheng earthquake of 1975, and smaller gravimetric changes associated with the catastrophic Tangshan earthquake of 1976, that was not predicted. It was suggested that these surprisingly large differences could have arisen from the movement of ground water. In the general discussion it emerged that although the immediate warnings before earthquakes were usually dependent on the occurrence of foreshocks, there has been at least one

case in Yunnan Province where this was given by other methods, such as variations in measurements of radon concentration in ground water, and resistivity.

Little was said about short-term precursors, but a new concept appears to be emerging for identifying 'precursory swarms' as a long-term indicator. This idea was most fully developed by F. F. Evison (Wellington) who elaborated an idea first published in *Nature* in April 1977. Evison's hypothesis is that a swarm of activity near the area of a forthcoming earthquake is followed by a 'precursory gap' which lasts until the occurrence of the 'major event'. As well as the position of the impending earthquake, its time of occurrence and magnitude are also indicated by the pattern of seismicity. It is still difficult to identify and interpret such swarms, and different criteria may be needed in different areas.

V. I. Keilis-Borok (Moscow) also spoke about the recognition of seismicity patterns before impending earthquakes. He postulated criteria for determining periods of 'activation' and 'quietness', rather analogous to Evison's concept, and also referred to precursory earthquake swarms. In reporting a detailed study of seismicity in the Aleutian Arc, Engdall and Kisslinger (Boulder, Colorado) also commented that they had observed similar patterns, and precursory variations in seismicity were observed by Talwani (South Carolina) in small earthquakes associated with a reservoir.

Other papers covered as diverse topics as the tilting of the Hawaiian Islands in relation to large circum-Pacific earthquakes, (Berg and Sutton, Honolulu), the prediction of intermediate-depth Romanian earthquakes by assigning time-series to historical events (Purcaru, Frankfurt), and the theory of deciding what constitutes an 'anomalous' reading (Jackson and Ergas, Los Angeles). It was also pleasing to note speakers presenting what seem to be negative results. Susan Raikes (Pasadena) reported a very thorough study of P-wave residuals in Southern California, revealing no anomalies. Dolbilkina and others reported that Soviet workers also often failed to detect precursory velocity anomalies, but a small change was found by a refraction survey near a large earthquake in Kamchatka.

Earthquake prediction still awaits a major breakthrough. It now seems however, that the best prospects remain the study of seismicity patterns, with the new concept of precursory swarms for the establishing of long-term predictions, and a fuller understanding of methods used by the Chinese for the issuing of final and short-term predictions. □

review article

Decision making in animals

D. J. McFarland*

Animals must make decisions about when to feed, when to court, when to sleep, and so on, in such a way as to maximise as far as possible their chances of survival and reproductive success. It is possible to formulate in mathematical terms the optimal strategy for an animal to pursue. The theoretical optimum behaviour can be compared with the actual behaviour of the animal, and perhaps shed some light on the evolution of behaviour.

At any particular time there are many activities in which an animal could engage: feeding, courtship, sleep, and so on. It is usually impossible for an animal to carry out such different activities simultaneously, because the required movements are mutually incompatible. There must be some process or mechanism that determines which activity is to have priority at any particular time, and such a process is conveniently termed a decision process.

The decisions made by animals may be decisions on whether to continue with current activity, or to change to some other form of behaviour. They may also be decisions between alternatives that present themselves anew. In each case, the animal has to assess a wide variety of factors. Consider, for example, the situation of a herring gull (*Larus argentatus*) incubating its eggs. Normally it will sit tight until relieved by its mate. Both parents incubate the eggs, and a nest left unattended is soon subject to predation by neighbours. It is important, therefore, that the sitting bird should not leave the nest before being relieved by its partner. This rarely happens under normal circumstances, unless the bird is flushed from the nest by a predator, such as a fox or a human. Studies of herring gulls, at the South Walney Nature Reserve in Cumbria, have shown that the non-sitting member of a pair is often foraging for food, or resting on the beach. It normally returns to the territory within a few hours of leaving. Sometimes, however, the return may be delayed as a result of some mishap, injury, or capture by a scientist. The sitting bird, with increasing hunger, should eventually decide to desert the nest, because herring gulls breed in many successive seasons and it may not be in the genetic interests of the individual to endanger its life for a single clutch of eggs. The timing of such decisions is a question that has interested students of animal behaviour in recent years.

The basic dilemma for the incubating gulls lies between the possibility that its partner may return at any time, and the increasing necessity to obtain food. The situation is complicated by the fact that the gull must assess the returns on time invested in foraging, which vary considerably with the weather, the state of the tide, and the time of day. Moreover, individual gulls tend to specialise in particular types of foraging, so that the sitting gull should take account of its own foraging skills in assessing the likely returns from time spent foraging in different places.

Two questions posed by this example are of particular interest to ethologists: (1) how can we account for the decision processes involved? (2) how good are animals at making decisions of this complexity? The basic approaches to these questions stem from

decision theory, on the one hand, and the theory of natural selection, on the other. In recent years there has been some convergence between these two lines of thinking.

Decision theory

The study of decision making provides a meeting point for many disciplines: statistics, economics, philosophy, psychology and control engineering. In classical decision theory there are two important classes of variable. One, the subject's evaluation of the relative attractiveness of alternative choices, is called the utility. The other, called the (subjective) probability, concerns the subject's evaluation of the consequences of making each choice. Thus a man may wish to make a decision between going to a restaurant or to a cinema, in terms of the utility of each. He may also take account of the probability of the restaurant being expensive, or the film being poor.

Reports of attempts to investigate these elements of decision making make up a voluminous literature, but only recently has this work become directly relevant to animal behaviour.

The empirical approach to the relationship between decision theory and animal behaviour was initiated by Logan¹, who studied rats living in a box in which they had to work for any water they received by pressing a bar. The animals had to work on some specifiable terms for the water rewards. The terms were manipulated by varying the force required to depress the bar, the number of times the bar had to be pressed to obtain a reward, and the size of the reward. Logan found that the rats were sensitive to the details of the terms, in that daily water intake was reduced when any of the three aspects of the terms was increased. In later experiments, Logan² gave rats a choice between a large food reward following a small delay, and a small reward following a large delay. He was able to establish equivalent combinations that were described by 'indifference' functions, and by equations describing the relative incentive value of different amounts and delays of reward. He also gave rats a choice between constant food reward and a varied amount, or varied delay, of reward; thus introducing the concept of 'subjective probability' for the rat. In general, Logan's results were similar to those that would be expected by classical decision theory. The evidence subsequently obtained by psychologists^{3,4} and ethologists⁵, although often confounded by measurement problems⁶, tend to support the view that animals are capable of consistently evaluating alternatives and of maximising their combined value. Consideration from first principles⁷ gives rise to similar conclusions, but draws attention to some formidable problems. A simple everyday example may serve to illustrate these.

There is widespread agreement that an understanding of decision making can be gained from (1) the formulation of a

*Department of Zoology, University of Oxford, South Parks Road, Oxford, UK.

maximising principle, (2) the recognition that there will inevitably be some trade-off among various aspects of the problem, which will necessitate (3) the formulation of an optimality criterion. As an example, let us consider a university committee set up to review applications for a lectureship. Their maximising principle is to choose the best candidate, but the requirements of the post are such that there will inevitably be a trade-off between the teaching experience T and the research ability R of any given applicant. Suppose that the committee arrives at an agreed short list of two applicants A and B, and that they are able to score these for teaching and research, so that for applicant A, $T = 9$ and $R = 1$; while for applicant B, $T = 2$ and $R = 7$. Any assessment of an applicant's overall strength of candidature must rest on the optimality criterion used to evaluate teaching experience in relation to research ability. For example, if the criterion implies that strength of candidature $C = T + R$, then applicant A would score $C = 9 + 1 = 10$, while for applicant B, $C = 2 + 7 = 9$. On the other hand, if we let $C = T \times R$, then A scores $C = 9 \times 1 = 9$, while B scores $C = 2 \times 7 = 14$. Clearly, by altering the optimality criterion, without changing the scores, it is possible to come to a different conclusion as to which is the best applicant.

We now have to ask what factors influence the optimality criteria. In the university context, factors such as government attitude, financial pressures, and so forth, are likely to determine policy concerning the balance between teaching and research. As far as the selection committee is concerned these are ecological factors. An overriding influence will be the

climate of ideas concerning the maximising principle. While in some universities the best candidate is seen in academic terms, in others it may seem to appoint the youngest candidate, the most politically conformist, and so on.

Translation of this example into terminology relevant to animal behaviour is not difficult at a superficial level. For example, let us suppose that there are two main factors contributing to feeding tendency: degree of hunger, in terms of physiological requirement for food, and strength of food cues, in terms of the animal's estimate of the availability of food. There will be an optimality criterion combining these into an overall feeding tendency, similar to that combining teaching and research abilities into an overall strength of candidature. Any tendency to feed has to be weighed against tendencies for other types of behaviour, because it is important that the criteria determining the feeding tendency be related to the animal's needs as a whole. We should therefore expect the decision criteria for feeding to be shaped by natural selection in accordance with the animal's ecological circumstances. For example, where food availability is erratic, more weight should be given to cue strength, while the weight attached to hunger should be related to the animal's physiological tolerance. We now come up against a problem that has dogged animal psychology for many years. While there has been a great deal of research on specific 'drives', such as hunger, aggression, and sex, there has been relatively little work on the interactions between such systems. Yet it is obvious that an animal's various needs have to be delicately counterbalanced, and that there is a problem for nature in weighing one against the other. We may call this the trade-off problem.

In considering what an animal ought to do in a given situation, we have to remember that the various possible activities have different consequences, and most have both costs and benefits associated with them. Let us take, as an example, the courtship behaviour of the smooth newt (*Triturus vulgaris*). This has been the subject of intensive study by members of the Oxford Animal Behaviour Research Group, supported by the Science Research Council, and aided by various university colleagues.

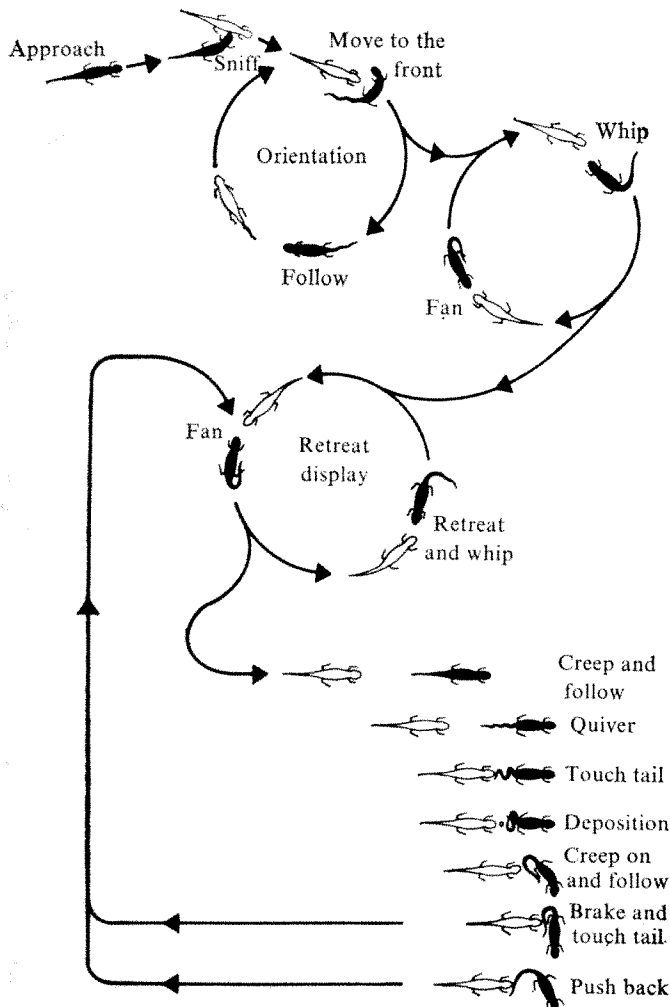

The courtship takes place on the bottom of a pond and is frequently interrupted by ascent to the surface of the water to breathe air. Observations show that the male newt breathes less often during courtship than he does normally. After the male has been to the surface of the pond to breathe he may be unable to find the female again when he returns to the bottom. Clearly, there is a cost associated with breathing during courtship, and it is not surprising that the males make breathing trips infrequently. However, although newts that are prevented from coming to the surface can probably remain alive by means of the oxygen dissolved in the water, they would be forced to become quiescent, so that courtship would no longer be possible. Thus there is also a cost associated with postponing breathing. The courtship of the male (Fig. 1) is designed to induce the female to pick up the spermatophore, which he deposits on the substratum. The female can only do this successfully if she follows the male closely. For this reason the courtship should not proceed too quickly, and the most successful courtships tend to be prolonged affairs. Thus, although the breathing problem can be alleviated by speeding up the courtship, this may make successful fertilisation less likely.

Mathematical formulation

Having touched on some of the problems involved in decision making in animals, we can now tackle the question of how we should aim to account for such decision processes.

It is difficult to foresee the day when the physiological analysis of behavioural control mechanisms will have advanced far enough to make much contribution to the explanation of decision making. Even if one knew all about the physiological mechanisms underlying breathing and courtship in newts, one would still not be able to predict when a male would decide to breathe rather than court a female. The decision will depend on

Fig. 1 A summary of the courtship behaviour of the smooth newt *Triturus vulgaris*. The black newt is the male. (From Halliday¹⁹.)

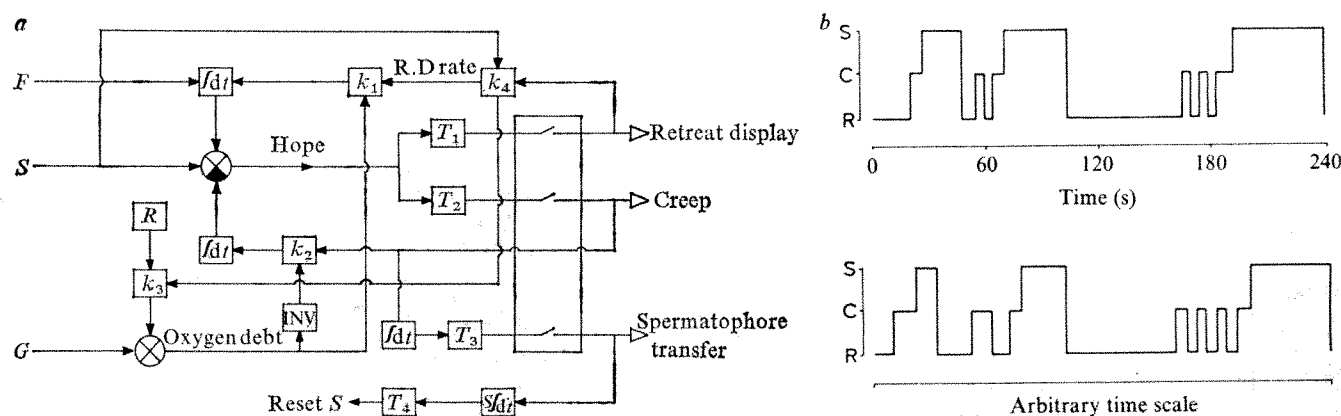

Fig. 2 a, A control model for the courtship of the male smooth newt. The following conventions have been observed: S, initial amount of sperm; F, initial sexual state of the female; G, initial value of oxygen debt; R, function representing the increase in oxygen debt with time; T_1 - T_4 , thresholds; k_1 - k_4 , modifiable parameters (modified from Houston *et al.*¹⁵); b, comparison of mean durations of various courtship activities of 22 newts (above) with that of the model (a). R, Retreat display; C, creep; S, spermatophore transfer phase (From Houston *et al.*¹⁵).

how the animal balances the two tendencies against one another. We would expect the balance to be influenced by both proximal circumstances and ultimate ecological considerations. The difficulty is that physiological knowledge is essentially piecemeal, whereas the decision problem is holistic.

The traditional behavioural analysis of preference and choice is equally inadequate in accounting for decision making as a function of time. The main reasons for this are that such theory takes no account of the ecological relevance of the behaviour, and is often attempting to account for processes which are in principle unobservable from the viewpoint of the psychological experimenter⁸.

Clearly, as has long been recognised by economists, some kind of abstract mathematical formulation is required to handle situations of such complexity. The difficulty lies in relating mathematical formulae to physiological and behavioural reality. In recent years there has been considerable progress in this area, by physiologists and behavioural scientists, who have embraced various types of systems analysis. The approach adopted by our research group is to represent the motivational state of the animal by the vector x , envisaged as a point in a multidimensional space. The state is influenced both by events internal to the animal, and by the external stimuli perceived by the animal. The changes in motivation induced as a consequence of behaviour trace a trajectory in the motivational space⁷.

It is traditional to view the motivational state of an animal as driving the behaviour, or as the input to a control system of which behaviour is the output⁹. However, an alternative approach is to regard the behaviour as the input which controls the state of the system by virtue of its consequences. In other words, the animal is seen as controlling its own internal state through the medium of behaviour, in accordance with built-in optimal design principles. Optimal performance is attained by reference to an optimality criterion that is embodied in an objective function, which is a function of the state x and of the behaviour u , where u is a vector representing the current behaviour in a behaviour-repertoire space. The objective function incorporates the optimality criterion represented as a set of trade-off relationships between the state and behaviour of the animal and their associated costs and benefits. In other words it specifies the (supposed) net cost of being in a particular state, and net benefit of doing a particular behaviour pattern under a given set of circumstances. The objective function is envisaged as a property of the individual animal, presumably genetically determined, and possibly modifiable by learning. Thus objective functions are expected to differ from one individual to another, although they may be similar in related individuals.

We can imagine the animal's brain as controlling the state of its body. Since every behaviour u results in a change in bodily

state x , the situation is akin to that found in man-made process-control problems, where the state of the plant x is influenced by extrinsic factors, and by the controller u , which is designed to achieve some optimal condition of the plant. For this reason the equations, which relate the ever-changing consequences of behaviour to the resulting changes in x , are called the plant equations.

The optimal control problem is to deploy the behaviour u in such a way that a particular state function, generally called a Hamiltonian H , is maximised at every point along the resulting trajectory. In other words, the animal is designed to deploy its behavioural options in a manner which continuously maximises the Hamiltonian

$$H = \sum_{i=1}^n \frac{\delta K}{\delta x_i} x_i - K = \text{plant equations—objective function}$$

The argument underlying this formulation is derived from decision theory, in which, as outlined above, the essential ingredients are the assumption of a maximising principle, and the formulation of an hypothesis relating to the objective function. This hypothesis can be tested by direct observation of the animal. As an example, let us return to the courtship of the male smooth newt (*Triturus vulgaris*). On the basis of a number of elegant experiments by Halliday¹⁰⁻¹², a deterministic control model was formulated by Houston *et al.*¹³, which accurately simulates the timing of the courtship sequence (Fig. 2). This computer model provides the information required to derive the Hamiltonian equations, which will predict the behaviour on the basis of its associated costs and benefits. The next task is to formulate the plant equations and find an objective function which satisfies the Hamiltonian formulation. On the assumption that the courtship of the male newt is designed to maximise the probability of successful fertilisation of the female, Dempster¹⁴ proposed the formulation illustrated in Scheme 1.

A prime feature of the courtship is that it takes place under water, and this means that the oxygen supply of the male is a most important factor. Indeed, the causal model (Fig. 2) shows that oxygen debt is the variable primarily responsible for modulating the temporal organisation of the courtship sequence, and this has been confirmed empirically¹¹. The importance of oxygen supply is reflected in the plant equation (Fig. 3) which specifies only one state variable: oxygen debt x . Because the male can replenish his oxygen supply only by terminating the

Scheme 1 Simplified version of Dempster's¹⁶ formulation of the temporal organisation of the courtship of the male smooth newt, in terms of optimality theory.

Objective: Maximise likelihood of successful fertilisation

$$\int_0^{\infty} \{ \exp[-\Phi S(t)t] S(t)u_1(t)x(t) + S(t)u_3(t)x(t) \} dt$$

Plant equation:

$$\dot{x}(t) = -x(t)^{-\rho}u_2(t) + \theta$$

Work during courtship:

$$\frac{u_1(t)}{\delta} + \frac{u_2(t)}{\gamma} + \frac{u_3(t)}{\tau} \leq 1$$

Energy expended during courtship:

$$\int_0^{\infty} \left[\frac{u_1(t)}{\delta} + \frac{u_2(t)}{\gamma} + \frac{u_3(t)}{\tau} \right] dt \leq E$$

Hamiltonian:

$$H = e^{-\Phi S(t)t} S(t)u_1(t)x(t) + S(t)u_3(t)x(t) - F(t) \left[-x(t)^{-\rho}u_2(t) + \theta \right]$$

(Costate) Hamiltonian equation:

$$\dot{F}(t) = \frac{\partial H}{\partial x} = e^{-\Phi S(t)t} S(t)u_1(t) - \rho \frac{F(t)}{x(t)^{1+\rho}} u_2(t) + S(t)u_3(t)$$

states: S = spermatophore count (0 - 3)
 x = oxygen 'debt'

controls: u_1 = rate of display behaviour (maximum rate δ)
 u_2 = rate of creep behaviour (maximum rate γ)
 u_3 = rate of spermatophore transfer (maximum rate τ)

parameters: Φ = basic discount rate of display behaviour
 ρ = control parameter for rate of decrease of x through skin respiration during creep behaviour
 θ = rate of increase of oxygen debt with time (during display and transfer behaviour)
 E = maximal energy expended in courtship
 F = costate variable = marginal value of likelihood of success per unit of x

courtship and visiting the surface of the pond to breath, there is effectively a fixed energy budget during courtship. Given that the courtship activities of the male have a "typical intensity"¹⁵, the fixed energy budget implies that there is a limited period of time available for effective courtship. During this time the male has to display to the female sufficiently to induce her to follow him closely during the spermatophore phase (Fig. 1), when it is essential that the female should correctly pick up the spermatophore, which is deposited by the male on the substratum. It is likely that coyness on the part of the females is a means of testing the suitability of the male as a genetic partner.

Early in the courtship there is a high probability that the female will depart from the scene to breathe, to feed, or to seek another male. As the male continues to display this probability decreases, and we can suppose that during the time available, R , this probability is given by $\phi e^{-\phi t}$. On this basis we can express the expected probability of fertilisation, given that the female is still involved in the courtship

$$\epsilon \int_0^T u_1(t) + e^{\Phi S(t)t} u_3(t) S(t)x(t) dt$$

This formulation implies that the importance of spermatophore transfer increases exponentially as the courtship proceeds.

The objective function (see box), therefore, takes account of the probability of the female departing, as well as the male's sperm supply S and oxygen debt x . The Hamiltonian, based upon this objective function and upon the plant equation specified below, gives rise to a Hamiltonian equation with a term for each of the three types of behaviour u_1 , u_2 , and u_3 . The optimal behaviour sequence is arrived at by the newt choosing to do that behaviour which has the larger term in the Hamiltonian equation. In doing this the newt is in effect choosing that activity which confers the greatest benefit in terms of maximising the probability of successful fertilisation.

This formulation has proved to be highly successful in predicting the timing of the courtship in a variety of conditions. It also makes some specific predictions about the physiology of the male newt. For example, during the vigorous display behaviour, the male's oxygen supply diminishes, but during creep behaviour the model requires that the oxygen supply increase to some extent. In fact, the creep behaviour is much less energetic than display, and it is entirely possible that oxygen supply can increase by means of skin respiration. This somewhat startling prediction implies that the male deploys the creep behaviour as a means of prolonging the courtship. Moreover, some such idea is necessary to explain the fact, illustrated in Fig. 2, that the male oscillates between creep and display more frequently in the later stages of the courtship session, when his oxygen supply is presumably lower. Of course the prediction that oxygen supply actually increases during creep behaviour should be put to the experimental test. It is reinforced, however, by the observation that this particular species of newt not only has a more prolonged courtship than related species, but also has a larger crest¹⁶, which probably enhances skin respiration.

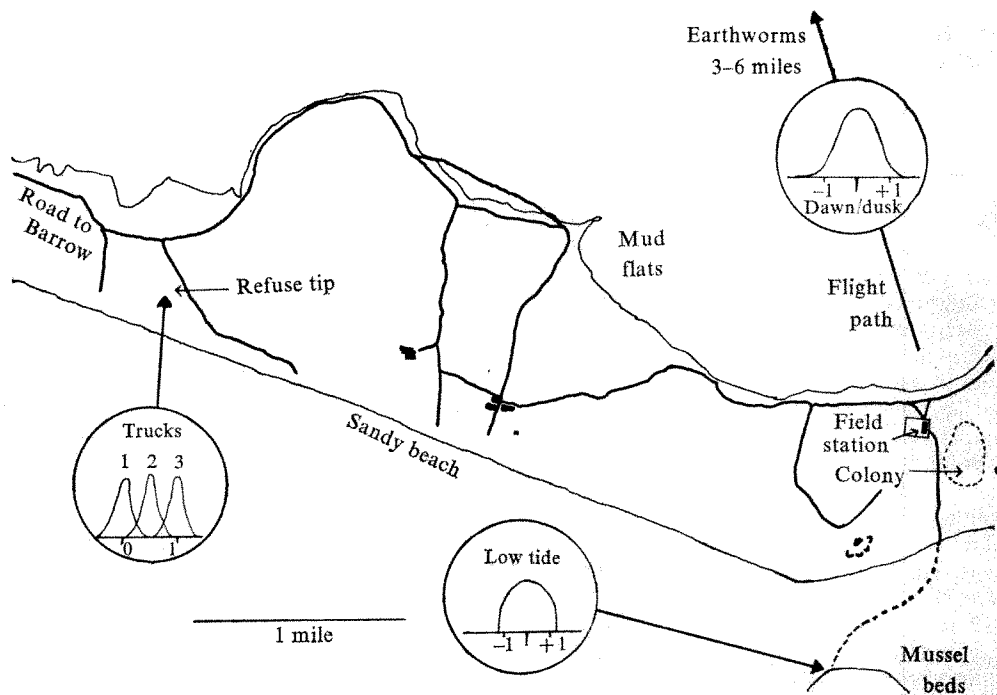

The reader may wonder why all this mathematical sophistication should be expended upon the courtship of newts. The answer is that so far newt courtship provides the most thoroughly worked test case of this general approach to animal decision making. This approach has widespread implications for theoretical biology, because it offers some insight into inverse optimality problems. Normal optimality problems pose the question of the best route to a goal, in particular circumstances. The inverse problem, which has been largely neglected by mathematicians, but is important for biologists, is that of what is being optimised by a particular structure, or a particular observed behaviour sequence. The general philosophy here is the following: if we know what a mechanism or system is designed to do, it will be much easier to find out how it works. In animal decision making it is essential to know that the decisions are about, before attempting to account for the mechanisms involved.

Natural selection

As biologists, we can expect natural selection to shape the decision-making processes of animals in such a way that the resultant behaviour sequences are optimally adapted to the current environmental circumstances. In other words, we can regard natural selection as a designing agent capable of producing the optimal design for any given set of conditions. Such considerations of optimal design apply just as much to the temporal organisation of behaviour as they do to the anatomical properties of animals. However, we cannot expect an individual animal always to behave optimally in its natural environment. Genetic variation between individuals, competition between individuals, the patchy nature of the environment, and changes in the nature of the environment, all combine to make it very unlikely that an individual animal can ever be perfectly adapted to its niche.

We can imagine, however, an 'ideal' animal that is perfectly adapted to its natural environment. The objective function of such an animal will be identical to a cost function, which is characteristic of the environment, in the sense that it reflects the selective pressures that moulded the objective function during the course of evolution. The cost function, therefore, specifies

Fig. 3 Map of part of Walney Island showing the positions of the most important feeding places in relation to the colony. Circles enclose graphs showing rough estimates of food availability.

the instantaneous level of risk incurred by (and reproductive benefit available to) an animal in a particular internal state, engaged in a particular activity in a particular environment. Such an ideal animal, perfectly adapted to its environment, will deploy its behavioural options so as to maximise the Hamiltonian, and thereby achieve that behaviour sequence which maximises its inclusive fitness in the prevailing circumstances.

In practice, we can distinguish two procedures by which optimal behaviour sequences can be investigated. In the first, a maximisation principle is assumed, and a particular form of the objective function postulated. This hypothesis is then tested in laboratory experiments. Ability to reproduce the behaviour of the animal is then taken as evidence in favour of the postulated objective function. This is the strategy used in the analysis of newt courtship outlined above.

In the second approach, an attempt is made to measure the components of the cost function empirically, by means of observations and experiments made in the field. The aim in this type of study is to determine whether animals in a particular natural environment are deploying their behavioural options in the optimal manner. The Hamiltonian formulation can then be used to generate behaviour sequences, or strategies, for a given environment, provided that sufficient is known about the cost function characteristic of the environment, and the plant equations characteristic of the animal.

As an example, let us consider the herring gull incubating its eggs, mentioned at the beginning of this article. This situation is being studied in detail by members of the Oxford Animal Behaviour Research Group, notably R. McCleery and R. Sibly, supported by the Natural Environment Research Council. The animals are studied intensively during the 4-week incubation period, particular attention being given to three main problems.

First, the factors influencing the internal state, of which the most important is hunger, and those affecting the animal's estimate of the environmental situation, of which the weather and food supply are of prime importance, are incorporated in the plant equations for the incubating bird. As part of the assessment of the animal's internal state, the whole nest including the sitting bird is weighed continuously by means of an electrically monitored balance buried in the ground. The measurements obtained in this way are capable of providing information about the loss of weight during fasting, and the gain of weight after foraging, with an accuracy of ± 20 g.

The gulls have a variety of possible feeding sites, at various distances from the nest, as indicated in Fig. 3. The availability of food fluctuates considerably in any one location, so that the bird has to choose among a continuously varying pattern of possibilities (Fig. 4)¹⁸. The availability of food as a function of time is computed from the tide cycle, the work routine of the men at the nearby refuse tip, the behaviour of earthworms in response to the weather, and so on. The extent to which the

Fig. 4 Availability of food (above) during one week in the 1976 season, and (below) the foraging behaviour of one individual gull, record by radiotelemetry.

birds can exploit these opportunities depends on the willingness of the partner to take over the incubation duties, the probability of human interference near the feeding sites, and the vicissitudes of the weather. These variables are all monitored, either by direct observation, or by means of remote automatic monitoring devices. Weather variables, such as light intensity, wind speed, and so on, have a considerable influence on the foraging efficiency of the gulls, and must be an important factor in their foraging strategy. The returns that a gull can be expected to gain per unit time spent foraging are also estimated; by analysing samples of the food source, and checking this against regurgitations around the nest. All these factors taken together, when suitably calibrated and integrated with each other, can be used to obtain a good indication of the state of an individual bird in a given set of circumstances, and of the changes in state that are consequent on its behaviour.

• Second, the behaviour of the individual birds on the territory can be monitored by direct observation from hides. Each bird is fitted with a radio transmitter so that it can be followed in a Land Rover when it leaves the territory, usually to forage for food. The birds are conspicuously marked so that they can be recognised amongst the thousands of others. Typically, a bird will fly from the territory directly to its chosen feeding ground. It may spend one or two hours feeding, often in competition with other gulls. It will then often bathe and drink in a fresh water puddle, before taking a 'rest' on a quiet part of the beach, or in a field. Such rest periods are generally communal affairs, although interactions between individuals are few. A considerable amount of time is spent preening and the question of whether gulls sleep on such occasions is currently being investigated. After a few hours away from the territory, the gull invariably returns home and takes over the task of incubation, relieving its partner.

The third problem is the cost function, which is a function of both the internal state of the animal, and of its behaviour. Obviously, for an incubating bird there is a risk attached to being in a particular state of hunger. It is not that the animal is likely to die while sitting on the nest, but rather that it may not find food very easily when it leaves the nest. If the animal had a reliable supply of food it could afford to risk a higher level of hunger than if its foraging fortunes were uncertain. In our study we attempt to measure such risks experimentally by removing one of an incubating pair of gulls, and studying the condition and behaviour of the remaining bird.

Similarly, when a bird leaves the nest as a result of disturbance or when pressed by hunger, there is a chance that its eggs will be eaten by a neighbour. The risk of egg predation can be measured by removing both of the nest owners and measuring the survival time of the eggs. Every aspect of the behaviour also has risks and benefits attached to it. Thus a bird foraging on the refuse tip may be poisoned, a gull on the shore line may get oil on its feathers. There is also the energetic cost of each activity to be taken into account. By systematically evaluating the cost and benefits involved in the behavioural routines of both members of mated pairs of gulls we aim to arrive at a mathematical formulation of the cost function.

In real life, an animal has to decide whether to sleep, feed, groom, and so on, at any particular time. In addition to its motivational state and the strengths of its various behavioural tendencies, the decisions reached will be heavily influenced by the decision criteria embodied in the objective function. If I believe that animal behaviour is subject to natural selection, I must conclude that the objective function is shaped by natural selection, because the decision criteria strongly influence the order in which animals go about their daily tasks.

The animal can be seen as carrying out a cost-benefit analysis in making its decisions. If the animal is not closely adapted to its environment, it may not make the analysis correctly; that is its objective function may not conform to the cost function characteristic of the current environment. Nevertheless, the animal is still an optimising agent with respect to its own objective function.

I do not intend to suggest that the individual animal necessarily carries out the cost-benefit analysis in a cognitive fashion, although this may occur to some extent in intelligent animals. The form and pattern of the behaviour is the outcome of a design operation which aims at the optimal compromise between the competing selective pressures characteristic of the environment. Obviously in a non-stationary environment, there will be an advantage in organising the decision-making processes in a flexible manner. Thus we can expect the laws governing learning to be designed in such a way that they tend to shape the objective function of the individual, and make it more like the cost function of the current environment. To study such phenomena we have to know something about the make-up of the individual animal, and something about its ability to adapt to the environment. This is where the herring gull study is so instructive. There is no question that individuals differ greatly. Some specialise in foraging for mussels, others for crabs, using quite different techniques. Some specialise in stealing eggs and chicks from neighbours, and others have apprenticed themselves at the local corporation refuse tip. Indeed, an important aspect of the optimal decision-making approach, outlined in this article, is that attention is concentrated on the behaviour of individuals, in contrast to the more traditional approaches to the study of animal behaviour, which rely on statistical inferences based upon the study of large numbers of animals. This attention to detail is made possible by the fact that optimality theory provides a way in which precise mathematical functions can be used within the normal scientific framework of hypothesis, prediction, and test. Hypothesised functions, tailor-made for the individual animal, can be used in optimality computations to predict sequences of behaviour that should occur in observed circumstances and conditions, and these predictions can be compared with the behaviour observed in the field or laboratory.

What then is likely to be achieved by the application of optimality theory to animal decision making, or by empirical studies designed to test predictions of optimality theory? First, the development of the theory itself has proved to be extremely instructive in forging links between ecology and behaviour¹⁸, between behaviour and economics¹⁹, and between environmental physiology and behaviour⁶. As I have mentioned elsewhere²⁰, we are entering a new phase of interpretation of animal behaviour, in which the complexity of animals is taken as a challenge, rather than as an excuse for mysticism or for sceptical over-simplification.

Second, we cannot expect to understand decision-making processes without also appreciating the selective pressures that shaped them. In many areas of biology it is helpful to understand the function of the material being studied, but in decision making it is essential, because decisions inevitably reflect the trade-off and compromise among the design features of the animal. Optimality theory provides a self-checking procedure, which is a considerable improvement on the traditional open-ended approach to the survival value of behaviour⁹.

Third, empirical studies ought to be part of any mathematical approach to biology, where there is a strong temptation towards arm-chair theorising. These studies should tell us, not merely whether the theory is right or wrong, since it is bound to be wrong in some respects, but also something about the mental competence of the animal themselves. Already we have seen that herring gulls adapt individually to their complex, ever shifting, circumstances. When we know more about how to account for the apparent decisions we observe and how good the animals are at matching their decisions to the real world, we may be in a position to investigate the mechanisms used by animals in adapting their time budgets to changing circumstances.

On the optical identifications of five X-ray sources

H. V. Bradt, K. M. V. Apparao*, G. W. Clark, R. Dower, R. Doxsey, D. R. Hearn, J. G. Jernigan, P. C. Joss, W. Mayer, J. McClintock & F. Walter†

Department of Physics and Center for Space Research, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

The data from a recently completed survey of the galactic plane with the SAS-3 modulation collimators provide precise (20"–60") celestial positions of galactic X-ray sources. Preliminary positions of 60" precision are reported for five sources. One of these led to the identification of the star, γ Cas, as an X-ray source, and the others lend substantial confidence to previously proposed optical identifications: 3U0352+30 = X Per, 3U1145–61 = HEN 715, GX301–2 = WRA977, and GX304–1 = MMV star. These identifications seem to establish the existence of a previously suggested class of De-star X-ray emitters.

THE SAS-3 X-ray astronomy observatory carries rotation modulation collimators (RMC) with which the positions of X-ray sources in the energy range 2–11 keV can be measured^{1,2} with a precision of 20" for the brighter sources³. In uncrowded regions, the detection threshold of a typical observation (1–2 d) is about 3 μ Jy (see footnote to Table 1). A programme of observations of the entire galactic plane ($|b^{\text{II}}| \lesssim 10^\circ$) has now been completed and the analysis is in progress.

The objective of this programme is the identification of radio, infrared and optical counterparts of the X-ray sources. At present there are about 10 well established identifications of stellar optical objects with hard (≥ 2 keV) X-ray sources. Most of these identifications are compelling because of positional coincidences coupled with coincident temporal phenomena such as identical orbital periods at both optical and X-ray wavelengths. A comparable number of additional identifications with varying degrees of confidence have also been proposed.

We describe here the survey of the galactic plane and present the results of five position measurements derived from it. One of these led to the identification of γ Cas as an X-ray source, and the others substantially increase our confidence in previously proposed identifications. These results are derived from the quick-look data and an early version of the analysis system which limits the positional precision to 1.0' (90% confidence). They have been announced earlier in preliminary forms^{5–8}.

Other early SAS-3 RMC positions have been reported for the

following galactic X-ray sources: Aql X-1, Ser X-1, GX9+9, and GX17+2 (ref. 9); 3U0143+61 and 3U1956+11 (ref. 10); Algol (ref. 2); MX1553–54 (ref. 11); the transients MX1803–24 (ref. 12), A1524–61 (ref. 13), and A0620–00 (ref. 1); the steady counterparts to two burst sources, 3U1733–27 (ref. 14) and A1905+00 (ref. 15); and the mid-galactic latitude source, 3U0044+32 (ref. 16). These and the positions reported herein constitute the first SAS-3 list ('1S') of galactic source positions. Subsequent papers will present '2S' positions as they become available. The latter will be derived from larger samples of data analysed with an improved system which yields the higher precision quoted above.

The galactic survey

The two SAS-3 modulation collimators have periodic triangular response functions of 2.3' and 4.5' FWHM respectively and $12^\circ \times 12^\circ$ FWHM fields of view. The celestial locations of the fields of view for the survey observations (Fig. 1) were chosen to yield two to three independent measurements of most sources and to provide substantial exposure to galactic latitudes $\pm 12^\circ$ in the region $-60^\circ < \ell^{\text{II}} < +40^\circ$ and $\pm 8^\circ$ elsewhere. The durations of the observations ranged from 0.5 to 2 d. Simultaneous X-ray data and optical aspect data which can be analysed for X-ray positions were obtained for about 30% of this time. Thus the useful duration of each observation ranged from $\sim 1 \times 10^4$ s to $\sim 5 \times 10^4$ s.

The celestial positions of the X-ray sources are derived from a cross-correlation analysis¹⁷ and a fast mapping algorithm. The

 $\dagger \mu\text{Jy} \equiv 1.000 \times 10^{-29}$ erg s $^{-1}$ cm $^{-2}$ Hz $^{-1}$ $= 2.418 \times 10^{-12}$ erg s $^{-1}$ cm $^{-2}$ keV $^{-1}$ $= 1.509 \times 10^{-3}$ keV s $^{-1}$ cm $^{-2}$ keV $^{-1}$ For a power-law spectrum of slope $\alpha = 1.08$ (for example, the Crab nebula⁴):1.0 μ Jy at 3.6 keV corresponds to an integrated flux of 0.96×10^{-11} erg s $^{-1}$ cm $^{-2}$ (2–6 keV) or ~ 0.6 Uhuru counts.1.0 μ Jy at 5.2 keV corresponds to 2.2×10^{-11} erg s $^{-1}$ cm $^{-2}$ (2–11 keV). I_{Crab} (3.6 keV) = 1,580 μ Jy; I_{Crab} (5.2 keV) = 1,060 μ Jy. \ddagger For the distances given in Table 2.

minimum intensity (counts cm $^{-2}$ s $^{-1}$) which is detectable in these cross-correlation 'maps' at the m standard deviation level can be shown to be $I_{\text{min}} = (m\pi^2/A) (B/8T)^{1/2}$ where B is the background rate (counts s $^{-1}$), A is the effective area at the peak of the response function (cm 2), and T is the effective observation time. An isolated source near the centre of the coarse field of view will be detected at the 7σ level ($m = 7$) in one of the two collimators ($A = 180$ cm 2 , $B = 30$ s $^{-1}$ and $T = 25,000$ s) if its intensity is

$$I_{\text{min}} = 4.7 \times 10^{-3} \text{ counts cm}^{-2} \text{ s}^{-1} \text{ (2–11 keV)}$$

$$\approx 2.3 \mu\text{Jy (2–11 keV)}$$

An intense source in the field of view will raise the effective background for the detection of a weak source. In the presence of a point-like source with the intensity of the Crab nebula at the centre of the field of view (380 counts s $^{-1}$, 2–11 keV), we have $\langle B \rangle = 30 + 380/2 = 220$ counts s $^{-1}$ and obtain $I_{\text{min}} = 6 \mu\text{Jy} (7\sigma)$. Furthermore, the bright source will exhibit a ring pattern which decreases in amplitude with radius from the source^{17,18}. This pattern can mask a nearby weak source, and therefore must be subtracted from the map¹⁷. This can be done with an uncertainty of $< 5\%$ of the bright source intensity. In our example, the residual rings from the 2.3' collimator, after subtraction of the Crab-like source, would have an amplitude of 5 μ Jy 1° from the source and 2 μ Jy at 5°.

Results

The position measurements reported here are summarised in Table 1. Characteristics of the optical candidates are summarised in Table 2 and finding charts are shown in Fig. 2. Of the five X-ray sources discussed here, one was identified in the course of this work (1S0053 + 604/ γ Cas), two were previously known and had convincing and well-studied optical counterparts (3U0352 + 30/X Per and GX301 – 2/WRA 977), and two have suggested counterparts which become credible with the present refined positions (3U1145 – 61/HEN 715 and GX304 – 1/MMV star).

Each of the positions was derived from at least four orbits of data and from both modulation collimators. Systematic errors in the positions dominate the statistical errors. We find the former to be no more than 30" to 40" based on observations of identified sources. Thus we report 60" error radii in this work as a conservative ($> 90\%$ confidence) estimate before the final analysis of the data. For each source, the multiple positions derived from individual orbits and collimators all lie well within this error circle.

The celestial areas defined by these circles are smaller by factors of 3–25 than the error regions obtained previously with the Uhuru¹⁹ and the Copernicus²⁰ satellites (see Fig. 2). In the case of 1S0053 + 604, there are no other position determinations of comparable precision. The proposed optical counterpart of each of the five sources lies within the SAS-3 error circle. The small error regions and the unusual character of these stars lend substantial confidence to the proposed identifications.

Table 2 Optical counterparts*

Star	Apparent magnitude	M_V	Type	Optical periods	Estimated distance	Angular distance from X-ray position

The five sources

X-ray emission from **IS0053+604**/ γ Cas was detected by SAS-3 during 30–31 December 1975 with both modulation collimators and the source was designated MX0053+60 (ref. 5). This source was the highest point ($\sim 15 \mu\text{Jy}$, 2–11 keV) in the $10^\circ \times 10^\circ$ field of the cross-correlation maps which were constructed from seven orbits of data (1.3×10^4 s). For Table 1, we assume the spectral shape of the Crab nebula and quote a 2–6 keV flux density of

$20 \mu\text{Jy}$. The X-ray position lies $10''$ from γ Cas which we identify as the optical counterpart.

An X-ray source, MX0049+59, was detected earlier with OSO-7, 1.3° or about three standard deviations from γ Cas (ref. 21). Independent X-ray observations of this region in December 1975 and January 1976 with the Copernicus satellite²² yielded a positive signal from the region of γ Cas with a 3° uncertainty in celestial position. The source intensities derived from these several

Fig. 2 The X-ray error regions (U = Uhuru, C = Copernicus, S = SAS-3) and the proposed optical counterparts for four of the five sources. X Per is the very bright star in the field; the other candidates are marked. The photograph for the X Per region is from the blue Palomar Sky Survey plate (National Geographic Society); for HEN 715 and WRA 977, from the ESO quick blue survey; for the Mason, Murdin, and Visvanathan (MMV) star²⁴, from a plate taken by Canizares and Hiltner with the 4-m telescope (V filter) at CTIO.

GX301-2 / WRA 977

GX304-1 / MMV star

observations are comparable, within about 50%. This supports the view that γ Cas is the only source in this region. The quoted intensities and the absence of an Uhuru sighting¹⁹ suggest that the intensity is variable.

γ Cas is a B0.5 (ii-V)e star with variable intensity ($V = 1.6$ – 3.0), variable line profiles, $M_V \sim -4.5$, and distance ~ 300 pc (see summaries in refs 23, 24). The spectral features indicate that the star is rotating rapidly, and variations of the emission line profiles suggest a 0.7-d period²⁵. It is an exceptionally variable Be star and in this respect is similar to X Per (ref. 23).

At the distance of 300 pc the 2–6 keV X-ray luminosity is $\sim 2 \times 10^{33}$ erg s⁻¹. A search for 44 Å emission by SAS-3 yielded an upper limit of ~ 130 μ Jy ($\sim 1/50$ the Cygnus Loop flux) in the energy ranges 0.10–0.28 keV and 0.4–0.8 keV. In the absence of a substantial interstellar cut off at ~ 0.6 keV, this limit and the 2–11-keV flux indicate a temperature $kT \gtrsim 1.5$ keV for a thermal spectrum, or a spectral index $\alpha \lesssim 1.0$ for a power law energy spectrum.

X rays from the 3U0352+30/X Per system were first detected with Uhuru at a 2–6-keV flux density of 35 μ Jy (ref. 19) and later with Ariel V at a comparable level²⁶. A 13.9-min X-ray period with peak-to-peak amplitude of 40% has been discovered²⁷. Also possible 22-h (or 11-h, ref. 27) and 581-d (ref. 28) periods have been reported. The X-ray source also exhibits irregular variability on time scales of minutes²⁹.

X Per, by far the brightest star in an early Uhuru error box, was proposed as the optical counterpart by several groups^{30–32}. A $V = 12$ star, ADS 2859B, which lies 22.5" from X Per has been suggested as the counterpart²³. The present results cannot exclude it. Its colours and spectrum indicate, however, that it is a normal M III star with no peculiarities which would suggest that it is the X-ray source³³.

X Per is rotating rapidly (~ 400 km s⁻¹, ref. 32) and is classified²³ as a 09.5 (III–V)e star with $M_V \sim -3.6$. Its intensity varies slowly on time scales of months or years from $V = 6.0$ to $V = 6.7$ (refs. 34, 29). Spectral studies yield evidence for a 584-d period³⁵, and narrow band photometry at 4,686 Å provides an indication of episodes of 13.9 min variability (ref. 36 and Canizares, personal communication). Searches for this episodic phenomenon on other occasions and by other observers have not yet confirmed it³⁷. Brucato and Kristian³² place X Per in the Perseus 2 association at a distance of 350 pc, which implies an X-ray luminosity of 5×10^{33} erg s⁻¹.

The 3U1145–61/HEN 715 system has a maximum X-ray flux density of 120 μ Jy (2–6 keV) which is variable by a factor of 5 (ref. 19). The B-emission star HEN 715 (SAO 251595) has been suggested previously as a candidate on the basis of the Uhuru position^{38–40}. It is relatively bright ($V = 8.95$) and blue ($B - V = 0.2$, $U - B = -0.85$) and exhibits fluctuations in brightness ($\Delta B \approx 0.02$, ref. 39). Its spectral classification is B1 Vne (ref. 41). We estimate the distance of this star to be 1.5 kpc if its luminosity is that of a B1 main-sequence star. This leads to a maximum luminosity of 3×10^{35} erg s⁻¹.

The GX301–2/WRA 977 system was first detected by Lewin *et al.*⁴² and McClintock *et al.*⁴³ during balloon observations which showed the source to be bright and variable in intensity by a factor of > 20 at high X-ray energies (< 10 – 200 μ Jy, 18–36 keV, ref. 44). At 2–6 keV, it is relatively weak (50 μ Jy) and variable by a factor of 3 (ref. 19). More recently, it has been found to exhibit an X-ray periodicity of 11.6 min (ref. 45) and to feature a strong iron absorption edge in its spectrum⁴⁶.

The emission line star WRA 977 ($V = 10.84$) has been proposed by Vidal⁴⁷ and Jones *et al.*³⁹ to be the optical counterpart. The star is heavily reddened ($E_{B-V} = 1.8$). The B1.51a classification suggests an absolute magnitude $M_V = -6$ and a distance of 2 kpc (ref. 47). This yields a 2–30-keV maximum X-ray luminosity of $\sim 4 \times 10^{36}$ erg s⁻¹.

At optical wavelengths, a tidal distortion light curve indicates a binary period of 23 ± 1 d (ref. 48). This has been confirmed by Petro (personal communication) who analysed a 3-yr compilation of photometric data provided by many observers. Finally, Mauder⁴⁹ reports that photometric data provide weak evidence

for the 11.6-min X-ray period. Thus, the established optical binary period of 23 d in WRA 977 has not been detected at X-ray wavelengths and the 11.6-min X-ray pulse period in GX301–2 has not been detected convincingly at optical wavelengths. It is our view, however, that the SAS-3 position removes any residual doubt about the identification of WRA 977 with GX301–2.

The GX304–1/MMV star system was first detected at X-ray wavelengths from balloons by Lewin *et al.*^{50, 51}. It is another of the small class of X-ray sources which have been detected at energies up to ~ 50 keV. Like GX301–2, it is highly variable in intensity at all energies. At 2–6 keV, its flux density is 80 μ Jy with a variability factor of 5 (ref. 19) and at 20–40 keV the factor is more than 7 (< 8 – 60 μ Jy, refs 43, 44). It has recently been found to be a slow X-ray pulsar with a period of 4.5 min (refs 52, 53).

The celestial region of this source is shown on a deep plate (Fig. 2) taken by Canizares and Hiltner at CT10 with the 4-m telescope. The marked star ($V = 14.72$ and $B - V = 1.80$) has been proposed by Mason, Murdin, and Visvanathan (MMV) as the optical counterpart⁵⁴. They report that this star exhibits H α emission with a FWHM of 700 km s⁻¹ and an equivalent width of 12 Å and that the absorption spectrum suggests a spectral type between B2 and A0. We do not attempt to estimate the distance to the star because it lies in a heavily obscured region of the sky (the Coalsack). It is unlikely that the bright star 1.5' south of this star is the counterpart as proposed earlier by Huckle *et al.*⁵³. It lies outside the conservative SAS-3 error circle and its colours do not suggest an early-type star (W.A. Hiltner, personal communication).

Discussion

These results seem to establish the existence of the class of accreting binary X-ray sources, suggested by Maraschi, Treves, and van den Heuvel⁴⁰, wherein the source of accreting material is a rapidly rotating main-sequence Be star. These authors propose that such stars with masses as low as 8 – $10 M_\odot$ could become X-ray sources through the accretion of circumstellar material on to a companion neutron star. They argue that the existence of such binary systems is reasonable from an evolutionary point of view.

The γ Cas, X Per and HEN 715 systems apparently belong to this class of X-ray emitters. The optical members are emission line, 09.5-B1, stars with luminosity classifications which are consistent with main-sequence membership. Two of these, γ Cas and X Per, are known to be rapid rotators^{25, 32}, with angular velocities that may be sufficient to yield approximately zero effective gravity in the equatorial regions^{25, 40}.

The spinup rate of the 13.9-min X-ray pulsar in the X Per system indicates that the compact accreting companion is a neutron star and not a white dwarf²⁸, although the latter would be consistent with the low X-ray luminosity^{55, 56}. The similarity between the X Per and γ Cas systems in X-ray luminosity, absolute magnitude, and in their unusually large optical variability²³ suggests that γ Cas also has a compact companion undergoing accretion. The nature of the compact member would be clarified if the system is found to exhibit periodic X-ray pulsations. Optical studies of these two stars do not exclude the existence of low-mass ($< 2 M_\odot$) secondaries^{24, 57}.

The data indicate that this type of system can give rise to an unusually low luminosity ($L_x \sim 10^{33}$ – 10^{34} erg s⁻¹) compared with that of other hard (> 2 keV) galactic X-ray sources (10^{35} – 10^{39} erg s⁻¹). The only other known example of such a low luminosity is Algol (ref. 2) with $L_x \sim 1.6 \times 10^{31}$ erg s⁻¹. This radio flaring object^{58, 59} is probably a very different type of system⁶⁰.

In contrast to the Be main-sequence stars, WRA 977 is a supergiant. Its X-ray partner is a slow pulsator with a luminosity which is quite high ($\sim 4 \times 10^{36}$ erg s⁻¹) and variable. This system is similar to the well known pulsating X-ray binary systems, 3U0900–40 and SMC X-1. It is well established that the X-ray emission from these objects arises from accretion on to a rotating magnetised neutron star (see refs 61, 62). Both a stellar wind and overflow of material from a critical potential lobe may be involved^{63, 64}. The extremely hard and variable X-ray spectrum of GX301–2 is unusual even among these sources^{65, 66}.

The X-ray source GX304–1 is similar to GX301–2 in that it has

a hard spectrum, a variable intensity at all energies and is also a slow X-ray pulsar. The tentative classification of its optical partner as B2 to A0 with a broadened H α emission line⁵⁴ suggests, however, that this might be another example of the Be-star systems discussed above.

We thank C. Canizares, J. Delvaille, A. Epstein, W. A. Hiltner, W. Lewin, L. Petro, S. Rappaport, and H. Schnopper for discussions and the staffs of the Center for Space Research at MIT and of Goddard Space Flight Center of NASA for their support. This work was supported in part by the US NASA under contact NAS5-1140. P.C.J. is an Alfred P. Sloan research fellow. This article is the first in a series on positions of galactic X-ray sources obtained with SAS-3.

Generation of Icelandic rhyolites by melting of plagiogranites in the oceanic layer

Haraldur Sigurdsson

Graduate School of Oceanography, University of Rhode Island, Kingston, Rhode Island 02881

Trondhjemite and quartz diorite xenoliths ejected in recent Icelandic eruptions are believed to be derived from plagiogranites within layer 3, formed by fractional crystallisation of basaltic magmas in the lower crust. Evidence indicates that rift jumping to older crust can lead to partial melting of plagiogranites at depth and their eruption as rhyolitic magmas.

THE volume of rhyolites exposed within the lava pile in Iceland is disproportionately large (10%), with individual rhyolite complexes covering areas up to 450 km² (refs 1, 2). The pronounced bimodal compositional distribution of basic and acid extrusives (Fig. 1) suggests, furthermore, that a process of shallow-level fractional crystallisation in subvolcanic magma chambers cannot alone account for the origin of these acid magmas. The ⁸⁷Sr/⁸⁶Sr and Pb-isotopic evidence³⁻⁵, however, precludes the possibility of generation of the Icelandic rhyolites by fusion of old continental crustal material at depth. An alternative model has recently been proposed⁶⁻¹⁰ to account for the origin of the Icelandic rhyolites by hydrous partial melting of basalts within the crust. This hypothesis is inspired by the experimental work of Kushiro^{11,12} on the synthetic system Di-Fo-SiO₂-H₂O at 20 kbar, where a silica-rich liquid was generated at 960 °C. There are three principal obstacles to deriving Icelandic rhyolites by hydrous anatexis of basalts within the crust.

(1) The process dictates that the resulting acid melts be H₂O saturated, contrary to the evidence of Icelandic rhyolites which are often extruded as dry obsidian lavas or solidify at shallow levels as pyroxene-bearing granophyres, lacking hydrous phases. Many rhyolitic eruptions in Iceland are, of course, violently explosive events, clearly associated with a water-rich vapour phase. The oxygen isotope evidence is consistent with incorporation of some low-¹⁸O meteoric water into these magmas. Oxygen-isotope geochemistry of the acid rocks^{10,13} shows that the tephra products of acid explosive eruptions have $\delta^{18}\text{O}$ in the 0.4-2.5‰ range, whereas obsidian and rhyolite lavas have $\delta^{18}\text{O}$ values of 4-6 ‰. Thus the data are in agreement with the idea that the water-propellant of acid explosive eruptions in Iceland is largely meteoric water which has diffused into acid magma in subvolcanic magma chambers¹⁴.

(2) Anatexis of basalt in the presence of H₂O at pressures comparable with the lower Icelandic crust (5 kbar) generates andesitic and dacitic melts analogous to the calc-alkaline suite of island-arcs¹⁵ and unlike Icelandic rhyolites (Fig. 2).

(3) No field evidence has been presented so far for the existence of amphibolites or other suitable metabasite starting material under Iceland, nor have xenoliths of possible refractory phases of this process been erupted.

An alternative model proposed here for the origin of Icelandic rhyolites is the melting of plagiogranites within the oceanic layer. By analogy with ophiolite complexes¹⁷⁻²⁴

and petrological models of the oceanic crust^{20,21,25}, it is proposed that layer 3 under Iceland is composed of layered (cumulate) mafic rocks at the base, overlain by gabbros which grade upwards into leucocratic differentiates: trondjemites and quartz diorites. This model of the oceanic layer under Iceland is supported by the ejection of plagiogranite xenoliths in several recent eruptions and the occurrence of plagiogranites in ophiolite sequences. The model is also consistent with the geochemical evidence, such as the bimodal compositional distribution of Icelandic volcanics and the dry character of the rhyolites.

Icelandic plagiogranite xenoliths

Fragments of leucocratic rocks have been ejected in a number of recent eruptions in Iceland, notably the 1963–67 eruption of Surtsey and the 1875 plinian eruption of Askja. Most finds are in basaltic scoria cones in the eastern and Snaefellsnes zones, that is, outside the western volcanic zone²⁶. Most Surtsey xenoliths have undergone extensive partial fusion and assimilation of the acid liquid into the basaltic melt, leaving a refractory residue of anorthitic plagioclase, tridymite and more rarely cordierite and mulite. Study of leucocratic xenoliths from Surtsey has shown

Fig. 1 Bimodal distribution of SiO_2 in 542 chemical analyses of volcanic rocks from Iceland.

that a complete gradation exists between anorthite-tridymite refractory assemblages and xenoliths of trondjemite and quartz diorite relatively unaffected by fusion²⁶. The texture of Icelandic plagiogranites is distinct from that of granophyres in Tertiary and Quaternary intrusive complexes exposed in eastern and western Iceland. The majority of the plagiogranite xenoliths contain 55–85% plagioclase, 10–35% quartz, minor clinopyroxene, K-feldspar, accessory zircon and variable amounts of intergranular pale brown to colourless glass. Plagioclase ranges from An_{26} to An_{44} and typical plagioclase composition in Surtsey xenoliths is $\text{An}_{35}\text{Ab}_{64}\text{Or}_1$. Plagioclase in Askja xenoliths is comparable but more potassic, with average composition of $\text{An}_{43}\text{Ab}_{55}\text{Or}_2$. Rounded grains of magnetite and augite ($\text{Wo}_{42}\text{En}_{34}\text{Fs}_{24}$) are the sole remnants of ferromagnesian minerals in the Surtsey xenoliths. Xenoliths from Snaefellsnes, and rare fragments from Surtsey, are granodiorites, with up to 25% K-feldspar in the mode, as reflected in their higher K_2O (ref. 28). The Icelandic

plagiogranite xenoliths are in varying stages of fusion, ranging from trondjemites with minor intergranular glassy films, to white frothy blocks consisting largely of very vesicular glass with minor relict quartz and plagioclase. Microprobe analyses of intergranular glasses in xenoliths ejected in the Surtsey 1963 eruption and Askja 1875 eruption (Table 1) show the general similarity between these partial melts and Icelandic rhyolites. The similarity in composition of partial melt in the 1875 Askja plagiogranite xenoliths and the rhyolitic tephra which brought these fragments to the surface (Table 1) is particularly persuasive evidence of an origin of the Askja acid magma by fusion of plagiogranites at depth.

Fig. 2 Chemical variation in Icelandic volcanic rocks. Solid lines are the compositional trends of partial melts generated by anatexis of Hawaiian basalt at 5 kbar water pressure at the QFM and HM buffers¹⁶. Solid symbols mark the compositions of partial melts in plagiogranite xenoliths from Iceland (Table 1).

In Table 1 the composition of Icelandic plagiogranite xenoliths is compared with diorites from the Mid-Atlantic Ridge²⁷ and plagiogranites from ophiolite complexes¹⁹. It was suggested above that plagiogranites were formed during fractional crystallisation in magma chambers within the oceanic layer under Iceland. Direct evidence in support of this hypothesis is lacking, but it is, however, consistent with the high geothermal gradient²⁸, the ejection of cumulate gabbro nodules in Iceland^{20–31}, the geophysical structure of the lower crust, and the evidence from ophiolite complexes.

Plagiogranites in ophiolites

Most workers agree that ophiolites represent fragments of ancient lithosphere and thus provide important clues to the understanding of younger crust at modern spreading centres. Plagiogranites containing predominant zoned sodic plagioclase and quartz, with minor ferromagnesian minerals and rare K-feldspar, are a subordinate but persistent component of ophiolite sequences, occurring as discrete intrusive bodies of diffuse facies in upper part of layer 3 (refs 17, 18, 19, 22, 24, 25, 32). In the Vourinos ophiolite complex, for example, layered gabbros of the mafic zone grade upwards by increase in hornblende and quartz and decrease in pyroxenes into a 1 km thick massive layer of quartz diorite and hornblende diorite, making up over 6% of the complex¹⁹. Similar plagiogranites and other leucocratic rocks have also been dredged from the Mid-Atlantic Ridge^{27,33,34}, most notably 96 km west of the

ridge axis at 45°N. These quartz diorites and hornblende diorites are closely comparable with plagiogranites from ophiolites, both in chemistry and petrography (Table 1). The occurrence of plagiogranites in ophiolites and oceanic crust is best accounted for by a process of crystal fractionation of tholeiitic melts, operating in magma chambers within the oceanic layer^{18,19,27}. This concept is supported by the similarity in ⁸⁷Sr/⁸⁶Sr values of plagiogranites and associated gabbros^{32,33}. The negative Eu anomalies observed in plagiogranite REE patterns further show that plagioclase extraction has an important role in the differentiation process^{24,36}. The occurrence of plagioclase, olivine and clinopyroxene-cumulates or layered gabbros at the base of the mafic zone in ophiolite sequences is further evidence of crystal fractionation within layer 3.

Petrological model of the Icelandic crust

The layered structure of the Icelandic crust is broadly similar to that of the ocean floors, but differs in two important details. The Icelandic crust varies from 8 to 15 km—approximately two to three times the thickness of normal oceanic crust³⁷. Much of this thickening is due to layer 2 and has been attributed to higher rate of lava production from the Icelandic mantle plume than on normal ocean ridges^{38,39}, combined with relatively slow spreading rate. Layer 3 under Iceland is also thicker than in normal oceanic crust, and differs significantly in having lower average P-wave velocity (6.5 km s⁻¹) than the oceanic layer (6.73 km s⁻¹)³⁷. This lower velocity can only partly be explained by higher temperatures and can also be attributed to higher proportion of differentiated rocks. The inverse relationship between thickness of the oceanic

layer and spreading rate²⁰ has been attributed to more efficient diffusion of interstitial melts in cumulates forming at the base of the crust, resulting in more extensive differentiation and secondary enlargement of the oceanic layer in slow-spreading regions such as Iceland³². Thus the differences in crustal structure between Iceland and normal ocean ridges may be a matter of degree rather than differences in character.

The proposed petrological model of the Icelandic crust is shown in Fig. 3. Layers 1 and 2 (2.8–5.1 km s⁻¹) are equated mainly with downwarped basalt lavas, dipping towards the long-lived western volcanic zone, grading into a lava-dyke complex with depth^{25,40}. Layer 3 is equated with gabbros, associated cumulate layered gabbros and leucocratic differentiates, along the lines suggested by Cann²⁵ for the structure of the oceanic layer. This part of the crust is envisaged as forming from crystallisation of basaltic magma in magma chambers within layer 3, principally under the rift zone flanks, where crystal settling in lateral parts of the magma chamber will give rise to layered gabbros at the base of the crust. During episodes of rifting and magma injection into the crust, such as the current episode in the north-eastern volcanic zone⁴¹, fractionation of the basaltic magma will be limited in extent. Between episodes of magma input, however, differentiation will proceed by crystal settling of calcic plagioclase and minor clinopyroxene and olivine in stagnant cooling lateral zones, distant from the axial zone of magma injection, resulting in the formation of differentiates solidifying as quartz-diorites, diorites and trondhjemites above gabbros in layer 3. Differentiates are unlikely to form in the active zone of basaltic magma injection immediately

Fig. 3 Diagrammatic model of the crust in southern Iceland, based on the seismic structure³⁷, geological evidence of the lava pile⁴⁰ and modifications of the oceanic crust model of Cann²⁵. The younger eastern rift zone has transected older crust, resulting locally in generation of rhyolite magmas from the partial melting of plagiogranites within layer 3 by ascending basaltic magmas.

under a rift, and are envisaged as forming rather within the upper part of layer 3, some kilometres away from the axial zone.

Generation of rhyolite magma

In Iceland the distribution of rhyolites is closely associated with central volcanoes, where they make up to 20% of the exposed volcanics in many cases⁸. As pointed out by Sigvaldason⁷, the great majority of rhyolite-producing central volcanoes of Late Quaternary to Recent age occur in volcanic zones which have dissected and are underlain by older crust, such as the eastern rift zone and the Snaefellsnes volcanic zone. Rhyolites are, on the other hand, altogether absent from the rift zone of Reykjanes peninsula¹², a region underlain by young crust. The distribution of plagiogranite xenoliths follows a similar pattern. They are most numerous in the Snaefellsnes zone, where recent volcanism has penetrated 5–13-Myr-old crust¹³, and in the eastern zone, from Surtsey to Askja. Saemundsson¹⁴ has inferred that the northern part of the eastern zone was established in its present position 4 Myr ago, following rift-jumping from the west, on to 8-Myr-old crust in the east.

It is proposed that the majority of rhyolites erupted in the Quaternary to Recent volcanic zones in Iceland are generated by melting of plagiogranite within layer 3 during episodes of injection of basaltic magma into a rift zone recently established within older crust. The availability of plagiogranites for this melting process is, however, limited to regions of older crust. Rhyolitic volcanism of this type is then restricted to regions of rift jumping, where a younger rifting episode transects older crust containing a differentiated gabbroic sequence with overlying plagiogranites. The structural and time relationships of individual rhyolitic centres are rarely known in sufficient detail to test this model. The well-studied Hallarmuli central volcano in western Iceland is a good case in point, however. Johannesson⁸ has shown that the earliest volcanics of this centre were acid ignimbrites erupted 6 Myr ago, on a 12.5-Myr basaltic crust. The model is also consistent with available geochemical evidence, such as measurable differences in ⁸⁷Sr/⁸⁶Sr ratio between rhyolites and field-associated basalts in the Torfajökull centre⁵. O'Nions and Gronvold⁵ pointed out that the present-day ⁸⁷Sr/⁸⁶Sr ratio of the rhyolites could be accounted for by postulating a 16-Myr-old source with initial Rb/Sr ratio of approximately 0.8. The observed range in Rb/Sr ratios of Icelandic plagiogranite xenoliths varies from 0.04 to 2.1 (ref. 26) and demonstrates the availability of such a source within older regions of the Icelandic crust. The large negative Eu anomaly in rare earth element (REE) patterns of Icelandic rhyolites⁵ is also comparable with the Eu anomaly in plagiogranites from ophiolite complexes^{24,32,36}, but the meagre data indicate lower overall REE abundances in the latter.

Implications of the proposed two-stage model for the origin of Icelandic rhyolites and petrological structure of the Icelandic crust are diverse. It is emphasised that the high volume of rhyolites erupted at the surface is not anomalous when considered in the framework of fractional crystallisation within layer 3. Furthermore, it is likely that the volume of rhyolites exposed at the surface in Iceland is not representative of their total volume in the crust as a whole, due to the possibility that the less dense rhyolitic melts will be preferentially concentrated at higher levels in the crust⁴⁵. If it is assumed, for purpose of illustration, that layers 1 and 2 are 4 km and layer 3 is 8 km thick, and that 10% of layers 1 and 2 are rhyolite, then formation of a salic differentiate residuum amounting to 5% of layer 3 would be required to form a plagiogranite source for the rhyolites. An important corollary of this model is that the basalt magmas which appear at the surface will in many cases have been modified by extensive fractional crystallisation², as the generation of leucocratic rocks within layer 3 is envisaged as a result of

differentiation of primary basaltic magma rising into the Icelandic crust. Also, it is likely that the heat required for partial melting of plagiogranite within older crustal regions is provided by extensive crystallisation of basaltic magmas in proximity with the leucocratic rocks. Thus basaltic lavas, associated with rhyolites which have originated in this way, are likely to be fractionation products of more primitive melts.

The mechanism envisaged for generation of Icelandic rhyolites is likely to be equally applicable to other oceanic hot-spots where rift-jumping has occurred. An appropriate example is the Easter Island region, where eastward jump of the Nazca-Pacific plate boundary has been documented⁴⁶. Taken together with the structural evidence, the marked chemical discontinuity between Easter Island rhyolites and associated basalts and the differences in ⁸⁷Sr/⁸⁶Sr ratio⁴⁷ suggest that Easter Island rhyolites may also owe their origin to fusion of plagiogranites within layer 3, as a consequence of rift-jumping. Similarly in the Azores region a marked bimodal compositional distribution exists between basalts and contemporaneous salic peralkaline lavas⁴⁸ where komendites have significantly higher ⁸⁷Sr/⁸⁶Sr ratios than associated basalts⁴⁹. Volcanism in the Azores islands is related to easterly trending fracture zones transecting older crust, generated at the Mid-Atlantic Ridge to the west. Thus the structural framework and geochemical evidence are also consistent with generation of the salic rocks in the Azores by remelting of plagiogranites at depth. Salic peralkaline lavas are volumetrically insignificant but widespread amongst oceanic islands. If their genesis can be interpreted in terms of partial fusion of plagiogranite within the oceanic layer, then is the cordierite–mullite refractory assemblage in the Icelandic xenoliths providing a clue to the origin of the peralkaline condition?

I thank R. S. J. Sparks for discussion. This research was supported by the US NSF.

Structure of nucleosome core particles of chromatin

J. T. Finch, L. C. Lutter, D. Rhodes, R. S. Brown, B. Rushton, M. Levitt & A. Klug

MRC Laboratory of Molecular Biology, Hills Road, Cambridge, UK

Crystals have been obtained of nucleosome cores and analysed by X-ray diffraction and electron microscopy. The core is a flat particle of dimensions about $110 \times 110 \times 57$ Å, somewhat wedge shaped, and strongly divided into two 'layers', consistent with the DNA being wound into about $1\frac{1}{2}$ turns of a flat super-helix of a pitch about 28 Å. The organisation of the DNA can be correlated with the results of enzyme digestion studies. A change in the screw of the DNA double helix on nucleosome formation can be deduced.

THERE is a good deal of evidence that, as proposed by Kornberg¹, chromatin consists of repeating units, termed nucleosomes, containing a fairly well defined length of DNA² (200 base pairs in rat liver³) associated with an octamer aggregate of the histones containing pairs of each of the four main types (for review see ref. 4). The fifth histone, H1, is also associated with the nucleosome, but in a manner which is not clear. Enzyme digestion studies on nuclei, using micrococcal nuclease, have shown that while the DNA content of nucleosomes is often about 200 base pairs, quite large variations are found according to the species or tissue investigated. But it has been found that further nuclease digestion produces a 'core' particle⁵⁻⁹ containing the same number, ~140 of base pairs in all cell types so far investigated. The rest of the DNA in the repeat length not included in the core is thought of as a linker between core particles. We report here the crystallisation of nucleosome core particles, and X-ray and electron microscopic studies on the crystals which have led to a low-resolution map of the structure. By combining this result with data from enzyme digestion studies on the DNA in nucleosomes and general considerations on the bending of DNA, we can obtain a picture of the organisation of DNA in a nucleosome core and a rationale for this organisation.

The work began following the discovery in this laboratory by Noll and Kornberg in 1974-75 that, on more prolonged digestion with micrococcal nuclease, the repeating unit of rat liver chromatin is broken down progressively from 200 base pairs of DNA. They found a pause in the digestion at the 160-base-pair stage and a longer one at 140 base pairs, between which stages histone H1 is released⁹. Early experiments on crystallising particles at the 160-140-base-pair stage were not successful, probably due to the presence of residual H1. It was not until the development of a method for the preparation of homogeneous nucleosome cores on a large scale for the purpose of biochemical studies (L.C.L., in preparation) that crystals could be regularly and reproducibly grown. Crystallisation of nucleosome cores has been reported previously⁷ but no analysis has been made.

Intact nucleosome cores have been crystallised and studied but we found that the best crystals so far obtained, which diffract to spacings of about 20 Å, come from particles which have had some of their histones cleaved by proteolysis. For the reasons given later we think that the core particles have not in consequence suffered

any significant change in structure, and that the results obtained are generally valid. The unit cell is large and contains three particles in the asymmetric unit, which then has a molecular weight of about 600,000, so that the solution of the structure by X-ray methods is a formidable task. For this reason the X-ray analysis has been carried out in conjunction with electron microscope studies on the crystals, and related aggregates, using methods of image reconstruction developed in this laboratory¹⁰. We have solved the three centro-symmetric projections of the crystal structure, and because one of them is down an axis looking through the width of only one particle, a fairly clear picture of the overall structure of the nucleosome core has emerged.

Preparation and characterisation of nucleosome cores

A detailed description of the preparation will be given elsewhere (L.C.L., in preparation). Essentially it involves preparation of nuclei from rat liver² and production of long chromatin from these nuclei by digestion with micrococcal nuclease¹¹. The long chromatin is then passed over a Sepharose 4B column equilibrated with 0.45 M NaCl to remove histone H1 as well as non-histone proteins, redigested with micrococcal nuclease and chromatographed on Sepharose 4B to produce a preparation of monomer core particles. The DNA of these cores is nominally 140 base pairs in length⁹. Polyacrylamide gel electrophoresis of the DNA from this preparation shows a single band, as seen in Fig. 1. When compared with the DNA from a DNase I digestion of chromatin, which contains a series of bands which differ by 10 bases¹², it can be seen that the monomer DNA has length distribution similar to that of a single DNase I-produced band; that is, less than ± 3 bases. The monomer preparation contains no histone H1 and usually contains normal amounts of histones H2A, H2B, H3 and H4 (Fig. 2).

These intact nucleosome cores almost invariably gave microcrystals as described below. But, the largest single crystals (Fig. 3) were obtained on occasions when the histones in the core particles showed extensive proteolysis (Fig. 2c, d). In most of these preparations the H3 and H2B bands have almost completely disappeared and new low molecular products are present. When this proteolysis occurred an endpoint seemed to be reached, as judged by the gel patterns. We have not investigated the nature of the products, but we believe that these partially proteolysed nucleosome cores are not much changed in their gross structure from the intact ones. First, the sedimentation constant of the proteolysed particle in 100 mM NaCl is hardly changed from the intact material (10.3S against 10.5S: we thank Dr P. J. G. Butler for these measurements). Second, brief DNase I digestion shows a pattern of bands every 10 bases (Fig. 1) which is very similar in its intensity distribution to that from intact particles, except that the rate of digestion of the proteolysed particles is higher. Moreover the relative frequencies of cutting at the individual sites, as determined by end-labelling experiments (see below), remain very similar for the proteolysed particles. Third, the crystal structures of the

Fig. 1 Polyacrylamide gel analysis of DNA in single stranded form from *a*, 140-base-pair nucleosome cores which gave the large crystals used for X-ray work (and in which some of the histones had been proteolytically cleaved, Fig. 2c); *b*, preparation (*a*) digested with DNase I; *c*, rat liver nuclei digested with DNase I. The DNase I digestion and gel electrophoresis were carried out as described in refs 3 and 9.

two are closely related. Furthermore, various preparations showing somewhat different patterns of proteolysis (for example, Fig. 2c, *d*) crystallised in identical forms, but with occasional differences in habit. For these reasons it is possible that the smaller fragments of the proteolysed histones (~1,000 to 3,000 molecular weight) which can be seen on the gel patterns are still present in the particles which have crystallised. If so, then the histone molecules on the core particle may not be much changed in tertiary structure, although some covalent linkages have been cleaved. This question is under investigation.

Crystallisation methods

The general methods used were similar to those described for crystallisation of various transfer RNAs in this laboratory^{13,14}. The 'monomer' peak from the Sepharose column was concentrated to about 3–6 mg ml⁻¹, and this solution was dialysed against a buffer containing 10mM Tris-HCl, pH 7.4, 0.2 mM EDTA, 0.1 mM phenylmethylsulphonyl fluoride and 0.3 mM azide. Crystals of the nucleosome cores have been obtained at both 4 °C and room temperature using a variety of components in the crystallisation mixture, but not enough experiments have been done so far to provide a phase diagram as complete as that for tRNA (ref. 14). The final concentration of the nucleosomes in the crystallisation mixture ranged from 0.5 to 2 mg ml⁻¹. Microcrystals and small single crystals were grown in the presence of 0.4–0.6 mM spermine tetrahydrochloride, or 3–4 mM MgCl₂ plus 0.2 mM spermine or else at 10 mM MgCl₂, 1.5 mM spermine and NaCl up to concentrations of 100 mM in 10% (w/v) hexan-1,6-diol. Small crystals were also grown in the presence of polyethyleneglycol 6000 (5–10%, w/v) which had the effect of reducing somewhat the concentration of Mg²⁺ and spermine required.

The crystals were grown either in drops in glass cavity slides, equilibrated against the organic solvents or in small

stopped glass tubes containing the appropriate mixtures. In both the vapour diffusion and direct addition methods, crystallisation occurred in 1–4 d.

Crystal packing

No large single crystals of intact material have yet been grown, but in the conditions described above microcrystals were obtained. X-ray diffraction 'powder' diagrams from these show three clear rings of spacings at 96, 55 and 37 Å and a fainter ring at about 29 Å. The first three spacings

Fig. 3 Crystals of nucleosome cores. The two larger ones are typical of those used for the single crystal X-ray diffraction work. Scale bar, 0.2 mm.

index on a two-dimensional hexagonal cell of side 110 Å, and correlate well with electron microscopic observations on the crystals which show extensive areas of a hexagonal arrangement of particles with this same cell side (Fig. 4). Such close packing is natural for particles with a circular shape. Although the micrograph showed these crystals to be several layers deep with the particles in register, so that the nucleosomes formed columns hexagonally packed, no obvious extra lines were found in the powder diagrams to indicate the inter-layer spacing. In view of the results described below, however, it seems likely that the inter-layer spacing is 57 Å—and so unresolved from the 55 Å ring for the basal hexagonal cell—and that the observed ring at 29 Å is its second order, since it definitely does not index on the hexagonal cell.

X-ray powder diagrams from small crystals of cleaved material show rings with the same spacings as the intact material but in addition, rings at spacings, 168, 72 and 50 Å, and other weaker unresolved rings. The significance of these became clear when crystals grew sufficiently large to be studied singly. To anticipate the results, these spacings reflect the fact that the cleaved core particles do not stack over each other in register but are displaced sideways to produce 'wavy' instead of straight, hexagonally packed columns. The largest crystals grew to about $200 \times 50 \times 20 \mu\text{m}$ in size and X-ray precession photographs were obtained. The X-ray patterns extend to spacings of about 20 Å and the patterns in the directions of the cell axes are shown in Fig. 5. At this stage we cannot tell whether the limit to the resolution is set by disorder in the crystals or by the combination of small crystal size and large unit cell. The crystals are orthorhombic of unit cell sides $a=110$ Å, $b=192$ Å and $c=340$ Å. The absence of odd index reflections along the directions of the reciprocal cell sides suggests that, at least to this resolution, the space group is $P2_12_12_1$. Most of the X-ray data out to spacings of 25 Å have been collected and a three-dimensional Patterson function calculated, the features of which are consistent with this space group.

The ratio of the cell sides $b:a$ is 1.74, very close to $\sqrt{3}=1.73$, suggesting a pseudo-hexagonal packing in the (001) plane, probably of columns spaced 110 Å apart. The high intensity of the 006 and 0012 reflections indicate strong subdivisions along the c axis of 57 and 28.5 Å, but there is no indication of a 110-Å subdivision in this direction in either the X-ray pattern or the Patterson. We therefore conclude that the units packed along a column are spaced 57 Å apart, and have a strong bipartite character in this direction. On this basis there would be 12 of these units per unit cell and these can be identified as nucleosome cores, since density measurements, although difficult with such small crystals, set

Fig. 4 Electron micrograph of crystal of nucleosome cores with intact histones, negatively stained with uranyl acetate. The cores are hexagonally packed with an interparticle distance of 110 Å. The dark centres indicate a lower density there than at higher radii. ($\times 300,000$).

limits of 9 and 14 for the number of particles in the cell. Twelve particles per unit cell means 3 in the asymmetric unit, which then has a molecular weight of 600,000.

Both the [100] and [010] X-ray photographs show strong reflections in the neighbourhood of the 006 and 0012 reflections, which, together with other features of the patterns, suggest that the columns of nucleosomes are not straight. The simplest interpretation¹³, confirmed later by electron microscopy, is that in the [010] projection, the columns of nucleosomes appear as approximate sine waves of period $c=340$ Å and amplitude about 14 Å, adjacent waves being approximately in phase. In the [100] projection, the columns are also sinusoidal with a period of 340 Å and amplitude about 8 Å, but adjacent waves are out of phase. Together the two projections imply that in three dimensions the line of particles in the z direction follows a sine wave lying in a plane rather than a helix. The projections of the sinusoidal columns down the z axis are elongated and there are two different directions of elongation in the unit cell. Hence although the centres of the projected columns lie on a hexagonal lattice, the packing is only pseudo-hexagonal, accounting for the presence in the [001] X-ray photograph of reflections with $h+k$ odd.

The chief differences in the 'powder' patterns from the intact and cleaved material can now be explained. In the crystals of the intact cores, the particles stack in register in the c direction, leading to straight rather than wavy columns (hence the absence of the 011 reflection at 168 Å). These columns are cylindrical when projected along the c axis, hence at low resolution the packing appears indistinguishable from hexagonal, whereas the wavy columns of the cleaved particles give an elliptical projection and hence stronger departures from hexagonality, exemplified by the 120 reflection at 72 Å. The straight columns of the intact material are divided into

Fig. 5 X-ray precession photographs of crystals of nucleosome cores taken in the directions of the unit cell sides a , [100]; b , [010]; c , [100].

57 Å and 28 Å spacings in the same way as is the cleaved, corresponding to the nucleosome spacing and its halving. This has been confirmed by recent X-ray photographs of single crystals of intact core particles which show the strong 00/ reflections corresponding to the thickness and bipartite nature of the nucleosome core. The *c*-axis repeat is now only 110 Å, corresponding to two nucleosomes 55 Å 'high', while the *a* and *b* axes remain the same.

Electron density map

The packing deduced from the X-ray data has been confirmed by electron microscopy. Patterns which can be identified with views of the crystal in the direction of the cell sides have been found in electron micrographs of fragments of crystals. Although there is considerable shrinkage particularly in the 340-Å direction (vacuum dried crystals visibly shrink some 10%–20% in this direction) the distribution of intensity in optical diffraction patterns made from the micrographs agree well with the low-angle part of the corresponding X-ray patterns. We have found images corresponding to the three principal projections, selected and processed the best of them using optical and computer methods for image analysis¹⁰. We have used the phases (signs in this case) of the reflections determined by computing the Fourier transforms of the images, with the amplitudes derived from the X-ray patterns to calculate electron density maps of the principal projections of the crystal structure. This analysis did not give the signs of some of the outermost strong reflections and we therefore assigned signs to make the three crystallographically independent particles in the unit cell as alike as possible. This use of 'non-crystallo-

graphic symmetry' is a compensating advantage of working with a large unit cell. A fuller account will be published elsewhere¹⁵.

In the [100] and [001] projections there is considerable overlap of units at different depths in the unit cell although in the former the sinusoidal columnar nature of the packing is evident and in the latter the pseudo hexagonal packing of the columns. The least overlap occurs in the [010] projection, the map of which is shown in Fig. 6. Wavy columns of particles, that is nucleosome cores, about 57 Å apart, are clearly visible. The density in each particle is strongly divided into two but the two halves are not always parallel to each other, so that the particle itself looks wedge shaped. Indeed the run of particles in an arc of the sine wave is reminiscent of the arrangement of voussoirs in an arch, but the map gives the impression that the three crystallographically independent cores do not all have quite the same rotational setting about the *c* direction.

The electron micrographs we have obtained of the crystals do not directly show much detail beyond the arrangement of the core particles. We have therefore searched for specimens which would show more details of the internal structure and so be compared with the map shown in Fig. 6. To this end we have set up specimens for crystallisation, examined them in the electron microscope before visible crystals appeared and found wavy columns of particles. Figure 7 shows some nested columns, similar to the packing which would exist in a section of the crystal perpendicular to the *y* axis and one layer thick. Along the columns, associated pairs of 27-Å striations are often clearly evident, but the nature of the

Fig. 6 Electron density map of the projection of the crystal of nucleosome cores in the direction of the *a* axis of the unit cell. The nine strongest amplitudes in the [100] X-ray diagram (Fig. 5a) out to spacings of 25 Å were included. The signs of seven of these were taken from the calculated Fourier transform of an electron micrograph of a crystal in the corresponding orientation. The signs of the remaining two amplitudes were chosen to make the three crystallographically independent particles in the asymmetric unit most nearly equivalent.

Fig. 7 Electron micrograph of columns of nucleosome cores formed after a short time in the conditions of crystallisation, negatively stained with uranyl acetate ($\times 300,000$). The wavy columns correspond to those along the *c* axis in the crystal (Fig. 6). They are about 100 Å in diameter and consist of stacks of bipartite nucleosome cores spaced about 55 Å apart. The two halves of the particles do not always appear parallel and are often V-shaped especially at bends in the columns. The fine details along the two halves of a particle are often related by mirror symmetry consistent with views of a particle with several radially directed pseudo-dyad axes.

pairing varies along the column. Sometimes the associated pair of striations are parallel but often they are not, giving a wedge-shaped appearance to the bipartite unit. In all of these cases, however, there is a strong tendency for the two halves to be related by approximate mirror symmetry, consistent with views at right angles to a twofold axis, or pseudo twofold axes, such as might arise from the arrangement of eight similar histone molecules about a true dyad.

Relation to small-angle scattering studies in solution

The flat shape seen for the nucleosome core is consistent with the determination of the volume and surface area of (intact) core particles by a model-independent analysis of small angle X-ray scattering data in solution (A. Tardieu and L. Sperling, in preparation). Whereas the radius of gyration (determined from the very low-angle data) would correspond to a uniform sphere of radius 57.6 Å, the surface area (determined from analysing the scattering curve to a resolution of 20 Å) would correspond to a sphere of radius 72 ± 5 Å, suggesting a shape departing markedly from the spherical.

There have been earlier proposals for a disk shape for the nucleosome core^{16,17}. The model calculations of the Searle group¹⁸ to explain their low angle X-ray and neutron scattering data in solution (to a resolution of about 30 Å) show that a flat particle fits the data well; and they have proposed a model for the core of the type we have found, although scattering in solution which yields spherical averages of intensities, can never prove a model. Only three dimensional data can resolve superposed intensities and give direction to dominant spacings observed.

Thus it can be seen that the 38-Å and 27-Å bands observed in X-ray scattering from nucleosome cores in solution (A. Tardieu and L. Sperling, in preparation), and also of course in whole chromatin, come from directions at right angles to each other. It is very likely that the 38-Å reflection which occurs in the plane of disk has a contribution from the second maximum of a Bessel function corresponding to the radius of the DNA, the first maximum being at 70 Å, which in the X-ray data appears as a broad shoulder superposed on the steeply falling part of the 'shape' scattering curve. But the 70-Å

maximum shows up clearly in the spherically averaged 'internal' scattering function deduced from neutron scattering using contrast variation¹⁹. The 27-Å band comes predominantly from internal structure along the axis of the short cylinder, corresponding to the spacing of the turns of the DNA superhelix. Again, this fluctuation of density is evident in the 'internal' structure function¹⁹. There is therefore no gross difference in structure between nucleosomes in solution and in the crystal.

There are also other obvious implications for interpreting the X-ray patterns from whole chromatin. Thus the crystal data shows that the well known '55-Å reflection' of chromatin in fact occurs in two directions at right angles (in the neighbourhood of the reflections 200 and 006) and has a quite different origin in the two cases, the first as a second order of the side to side spacing of the cores, and the second as the distance of contact between their flat faces. The first order of the side to side spacing at 110 Å is cancelled by the packing in the crystal but presumably corresponds to the '110-Å reflection' of chromatin.

Structure of nucleosome core

The most informative of the three projections we have obtained is that down the *a* axis (Fig. 6) because one is looking only through a single layer of particles with a little overlap at the edges. The nucleosome core is clearly a flat particle of dimensions $57 \times 110 \times 110$ Å but seems to have a wedge shape consistent with its being formed of something less than two superhelical turns of DNA wound on a flat histone core. Because of its shape we call it a platysome. Again, as described above for the electron micrographs, the two halves of a platysome in the map are related by approximate mirror symmetry, consistent with a dyad or pseudo-dyads in the plane of projection. This is consistent with a model in which two turns of DNA (strictly parts of two turns) run along the outside of a histone core which may itself consist of two layers or turns. At the present resolution, and also because one is dealing with a projection, one cannot distinguish DNA and protein, but the map is not consistent with a structure in which the DNA lies in a deep groove formed by the histones. Rather, the DNA is fitted on to the periphery of the histone octamer rather like a helical tyre. The location of the DNA on the outside of the nucleosome was originally suggested by Kornberg¹, and it has been confirmed by low-angle neutron scattering in solution that the bulk of the DNA does lie at an outer radius^{19,20}.

It is not possible at the present stage to follow the path of the DNA in the nucleosome core but the simplest assumption is that it follows a more or less regular helix. Whatever the details, the DNA is wound in a flat superhelix of pitch about 28 Å and average diameter about 90 Å (Fig. 8a). The value for the pitch comes from the side view of a particle in the electron density map (Fig. 6). The pitch of the superhelix is small enough to allow interactions between the two turns, mediated by cations and/or histone salt bridges. The diameter is fixed by the fact that the very outside diameter of a nucleosome core can at most be only 5 Å or so greater than the shortest centre-to-centre distance, which is not less than about 100 Å. The reason is that platysomes in neighbouring columns parallel to the *c* axis are staggered by only about 10 Å (Fig. 6) so there is not much interlocking which would have led to a larger diameter for the DNA. Assuming a diameter for the DNA of 22 Å the diameter for the DNA coil is about 90 Å, and if the DNA is assumed to be in the B form, we estimate there are 75–82 bases per superhelical turn.

Little can be concluded about the arrangement of histones. The dimensions of the histone core, deduced by

Fig. 8 *a* Diagram, drawn roughly to scale, of the $1\frac{1}{2}$ turns of the DNA superhelix proposed for the 140-base-pair nucleosome core. The top set of numbers gives the distances in bases of the DNase I cutting sites from the 5' end of one strand, and the bottom set refers to the other strand, related to the first by the dyad shown. For definiteness, the number of bases per turn is shown as 80, but the exact number is not established. *b*, The $1\frac{1}{2}$ turns of one strand of the DNA superhelix represented as a spiral to show how the supercoiling brings sites 80 bases apart close together and groups the sites of low or medium cutting frequency by DNase I into the two diametrically opposite areas A and B, shown shaded. The arrow indicates the dyad. The numbers give the distance in bases from the 5' end. ★, High frequency DNase I cutting. ●, Low (or micrococcal) pauses. ○, Medium.

'subtracting' the DNA, show the octamer to be a compact particle, of packing volume similar to that found for other globular protein aggregates such as haemoglobin. It is, however, not possible to tell whether the histone molecules form a shallow helical ramp of two turns or whether there are simply two layers which are distorted or have projections on them to provide such a helical ramp. There is a striking similarity between some of the dimensions which occur in the columns of nucleosomes found in the crystals and the spacings observed in optical diffraction patterns of electron micrographs of certain histone fibres assembled without DNA²¹. In the columns in the crystal the histone cores of adjacent platysomes must be in contact and the packing may be similar to that in the histone fibres. If this is so, the 28-Å group of reflections in the crystal (compare Fig. 5a) would have a contribution from the histone cores, which would thus also tend to be divided into two.

Relation to enzyme digestion studies

We now turn to the question of the organisation of the DNA in the nucleosome core, and show how our structural results can be correlated with the results of enzyme digestion studies. The action of DNase I on chromatin or nucleosome cores is to produce a set of DNA fragments differing in size by 10 bases¹², and this was interpreted as reflecting the fact that the enzyme either cuts at points on smoothly bent DNA which are 'maximally exposed' (that is, lie furthest from the centre of the particle) or at 'kinks' in the DNA where the structure is distorted. Whatever the explanation, the important fact is that periodicity along the DNA helix is 10 bases or very close to 10. It is clear, however, that the cuts are not equally frequent every 10 bases and the assumption is that frequency of cutting reflects differential protection of different tracts of the DNA by the histone interactions. Several studies have been made of the frequency distribution by radioactively labelling an end of the DNA in the 140 base-pair core, then digesting with DNase I, and then analysing the distribution of end-label amongst the single-stranded fragments produced (refs 22 and 23, and M. Noll in preparation). Numbering in bases from the 5' end, it is found that the sites at 10, 20, 40, 50, 90, 100, 120 and 130 are readily attacked, so that cuts tend to occur at 30–40 or 80–90 bases apart. There are quantitative differences in the results of the different investigators but the local rank order among the cuts is the same.

Now as stated earlier the diameter of the DNA coil is best fitted by about 80 bases per turn, so that points on the DNA double helix 80 bases apart are closest together on the superhelix, only about 30 Å apart, and can therefore be protected, or otherwise, by neighbouring patches of histones (Fig. 8b). The positions of the most frequent cuts are consistent with this, but would not in themselves rule out a periodicity of 90 bases. The decision in favour of 80 is, however, unambiguously made by considering the least frequently cut sites, which are at positions 30 and 110 and are flanked on both sides by sites of high frequency cutting. This reasoning can be extended to include the results of micrococcal digestion studies, which show a 'pause' at the 160 base-pair stage before the more stable 140 base pair particle is produced. If the 160-base-pair particle corresponded to a structure with two complete turns, (which can be recreated by extending the DNA of Fig. 8 from the points 0 and 140 to –10 and 150), then the sites at 0 and 140 reflect places of relatively high protection of the DNA. These two positions can be correlated with the weak DNase I cuts at 80 and 60 respectively, which are 80 bases away. Such a 160 base pair particle would have its two ends 'in line' with each other and with the midpoint of the DNA. Through the midpoint would pass the putative dyad of the structure. The other end of the dyad would pass between the turns of the DNA, that is, between sites 30 and 110 (Fig. 8a).

The DNase I cutting pattern is consistent with the assumption that the nucleosome core possesses a dyad and the matter is discussed in detail elsewhere²². If there is a dyad as shown in Fig. 8a, then if a cut occurs on one strand, it is equally likely that a cut occurs at the equivalent position on the other strand, that is at the same distance from the 5' end. But since what is measured is the average of the frequency of cutting on the two strands, it is not possible to tell whether the cutting is equally apportioned between the two. Crick has pointed out that the strongest evidence for a dyad comes from the fact that there are weak (or zero) cuts, as here cuts at equivalent positions on both strands must be both zero or small and hence equal. Apart from the histone composition there are other biochemical results suggesting the presence of a dyad. It has been shown²⁴ that DNase II can cut down the DNA of a 200-base-pair nucleosome into two equal halves without disrupting the particle physically and there is electron microscopic evidence that in

appropriate conditions a nucleosome can open up into two separate half-nucleosomes²⁵.

Supercoiling of the DNA

If DNA is closed into a circle after interaction with histones in the presence of a 'DNA relaxing' enzyme, the DNA is seen to supercoil when the histones are removed²⁶. Several workers have estimated that the 'number of supercoils' is between -1 and $-1\frac{1}{2}$ per nucleosome²⁶⁻²⁸ (the minus sign indicates left-handed supercoiling). It was pointed out by Crick²⁹ that what these experiments measure is the change in linkage number (here the number of times one strand of the DNA double helix is wound around the other strand) caused by forming nucleosomes. It is not possible by the techniques used to distinguish between the separate contributions made to the change in linkage number by the coiling of the DNA into a superhelix and by any concomitant change in the local twist of the DNA double helix. Only the sum is conserved. The change in linkage number is the same as the number of superhelical turns only if the screw of the DNA double helix does not change in the local coordinate frame defined by the superhelix path.

Our results on the crystals show that as the maximum DNA radius in the core particle is about 45 Å, the 140 base pairs of DNA must make more than $-1\frac{1}{2}$ turns of superhelix. In fact we propose $1\frac{1}{2}$ superhelical turns corresponding to 80 base pairs per turn. The only way to reconcile these results with the linkage number change of $-1\frac{1}{2}$ is to conclude that the helical screw of the DNA double helix does indeed change on binding DNA free in solution on to the nucleosome. It would be possible to calculate this change in screw if we knew to what length of DNA the observed linkage number change applied. If the full 200 base pairs of DNA in the chromatin repeat are wound superhelically in the nucleosome giving $-2\frac{1}{2}$ turns, the average screw rotation angle between bases must decrease by $(-1\frac{1}{2} + 2\frac{1}{2})/200 \times 360$ degrees ≈ 2.3 degrees. If only 140 base pairs of DNA are wound superhelically and the remaining 60 base pairs are straight as in solution, the decrease in screw angle is $(-1\frac{1}{2} + 1\frac{1}{2})/140 \times 360$ degrees ≈ 1.3 degrees. Now the DNase I cutting pattern strongly suggests that the number of base pairs per turn of DNA double helix on the nucleosome is close to 10 (36° base rotation). If so, the number of base pairs of DNA free in solution must be either 10.7 or 10.4, for these two models respectively (33.75° or 34.7° base rotation).

Now while it is commonly accepted that DNA has 10 base pairs per turn, this value comes from X-ray diffraction work on fibre patterns where the DNA is in a rather dry state and the crystal packing tends to produce an integral number of base pairs per turn. There is no reason to believe that this number must apply exactly to free DNA in solution and indeed it has been suggested³⁰ that the screw of the DNA in solution was closer to 11 base pairs per turn. The arguments are based on rather limited evidence from the position of the 12-Å peak, an experimental result which has been confirmed³¹, but which could have other explanations.

Energy calculations (M. L., in preparation) on double helical DNA show that DNA can be smoothly bent into a superhelix of radius 45 Å. The superhelical structure has a local geometry very like that of straight DNA and an energy only slightly higher than that of the straight structure. Furthermore, the straight DNA has the lowest energy with 10.7 base pairs per turn, whereas the superhelical DNA has the lowest energy with 10.0 base pairs per turn. The base pairs overlap less in the superhelically bent form to enable the base pairs to twist and tilt to accommodate the bending strain. These calculated values for the screw of straight and bent DNA are in good agreement

with the values deduced above from the combination of the results of quite different types of observation.

General features of the DNA folding

The calculations mentioned above show that it is not necessary, on merely energetic grounds, to postulate that the folding of the DNA on to the nucleosome requires sharp kinks^{32,33} at periodic intervals. Indeed, one can see *post hoc* the advantages of the nucleosome structure proposed here for folding a long, stiff molecule like DNA. It has been known for some time that DNA in solution behaves like a stiff rod (with a persistence length of 625 Å; ref. 34) but the energy calculations show that DNA can bend smoothly down to a radius of curvature of about 40 Å without undue strain (<3 kcal per 10 base pairs). Because the strain energy on bending increases as the inverse square of the radius of curvature, the superhelix should have as large a diameter as possible. One may ask then why the 140 base pairs are not merely bent into a single turn, apart from any extended protein arrangement this might require. The advantage of having more than one turn of superhelix for the DNA is that this makes it possible to have stabilising interactions between DNA in adjacent turns. The most obvious source of stabilisation would come from bridging negatively charged phosphate groups on the DNA by means of cations or positively charged histone side chains. The strength of this lateral interaction will depend on the length over which the two turns interact, the separation of adjacent turns, and the relative positions of the phosphate backbone in each turn. In the structure proposed here there are about two superhelical turns per nucleosome, which gives a full turn for lateral interactions, but still keeps the radius of curvature large. These turns are separated by about 28 Å, an ideal distance for repeated interactions between phosphate groups of double helices that are in phase. When the number of base pairs per turn of the double helix is integral (10 here) then the same stabilising interactions between adjacent superhelix turns can occur repeatedly along the chain.

How do H3 and H4 alone 'organise' the DNA?

There is a growing body of evidence^{25,35-38} that the DNA can be folded into a body with many of the features of the nucleosome core by the arginine-rich histones H3 and H4 without the intervention of the other two histones. Indeed, it was part of Kornberg's original reasoning that the arginine-rich tetramer formed the basis of the nucleosome, and that the lysine-rich histones completed the structure. The first evidence was provided by Felsenfeld and his colleagues as judged by the protection provided against micrococcal and other nucleases^{35,36} and more recently it has been demonstrated by Chambon and his colleagues²⁵ that distinct subnucleosomal particles of diameter about 80 Å can be formed by reconstitution with only the histones H3 and H4 and that these particles contain about 130 base pairs which have about the same amount of supercoiling as a complete nucleosome core containing all four histones. It also seems likely that it is only a single tetramer which is involved rather than a pair of tetramers simulating an octamer (P. Chambon, private communication; see also ref. 37).

The simplest explanation³⁵ for this sub-nucleosomal particle is that the 140 base pairs of DNA condense around a central core or kernel formed by the H3-H4 tetramer, but other more open structures are possible which take into account the stiffness of the DNA and which moreover can be regarded as incomplete nucleosome cores leading to the basic structure described here.

This may be accomplished in two ways. The first is that the H3-H4 tetramer is asymmetrically located in the

nucleosome, say in the region marked A in Fig. 8, and that this tetramer clamps together two turns near the positions marked 0, 70 and 140; this would be sufficient to impose the supercoiling. A single tetramer would not, however, give protection against nucleases to the DNA in the region B and moreover it is difficult to see how the appropriate length of the DNA would be determined. A second, attractive explanation attaches significance to the fact that the two main regions of protection of DNA by the histones lie diametrically opposite each other (A and B in Fig. 8b). The H3-H4 tetramer could span the diameter of the nucleosome core to act as a spool around which two turns of DNA could be wound. Reconstitution with the tetramer would then resemble wrapping a garden hose around one's forearm. This would have the advantage of additional protective interactions and at the same time measuring out the appropriate length of DNA. H2A and H2B would then complete the nucleosome.

There is an interesting parallel between the packing of DNA in eukaryotic chromosomes and in the nucleoid of *Escherichia coli*. In both cases there seems to be about one 'supercoil' (or rather change in linkage number) per 200 base pairs^{39,40}. The folding of the DNA in *E. coli* seems to be produced by a small basic protein⁴¹, which moreover is apparently a dimer (Rouvière-Yaniv, personal communication). One could imagine that the dimer clamps together two superhelical turns at one point as described above. As eukaryotes developed, further basic proteins may have been introduced to produce a more regular, better protected particle—the nucleosome—capable of being organised into higher order structures.

We thank Dr F. H. C. Crick for valuable discussions, Mr R. Staden for measuring the X-ray intensities and Dr A. Jack for computing the Patterson function. L.C.L. was supported by a US NIH postdoctoral fellowship.

Immunological selection of tumour cells which have lost SV40 antigen expression

P. T. Mora, C. Chang, L. Couvillion, J. M. Kuster & V. W. McFarland

Macromolecular Biology Section, National Cancer Institute, National Institutes of Health, Bethesda, Maryland 20014

In an already tumorigenic spontaneously transformed mouse cell, after further transformation by SV40, the virus-specific antigenic function becomes dominant. By transplantation into syngeneic mice SV40 antigen negative revertant tumour cells can be selected out.

THE nature and function of early proteins of oncogenic viruses are receiving considerable attention. For simian virus 40 (SV40) the early protein, coded by about half of the SV40 genome, has dual functions. One is apparently as a regulator protein with a crucial role in the induction of cell division, the initiation of viral DNA replication and in cell 'transformation'. The second is antigenic. In the transformed cells these two type of functions, paradoxically, may oppose each other *in vivo*. The transplantation antigen can be the cause of immunological recognition and rejection.

SV40 (virus), or cells transformed by SV40 in tissue culture are tumorigenic only in the newborn hamster and *Mastomys*. (*Rattus (Mastomys) natalensis* is an African rodent intermediate in size between the rat and the mouse.) Neither SV40 nor the cells transformed in culture by SV40 are as a rule tumorigenic in the mouse¹ or in the rat²,

or as far as it is known in any other species including the natural host of the virus the simian monkey. Tumours have been obtained in the mouse from SV40 transformed non producer cells, but only after considerable time and a number of tissue culture transfers (t.c.t. >50) followed the SV40 transformation step, and when relatively large number of cells (about 10⁶) were injected^{3–5}. Even then, most of the tumours were transitory, and were eventually rejected by the mice^{3–6}. If the immunological competence of the mouse is weak, like in the newborn, or is impaired (by, for example, irradiation, anti-lymphocyte serum, or neonatal thymectomy) SV40 T antigen-positive tumours may be produced more readily than in the immunologically competent syngeneic mouse^{4,7}. Such tumours then become retransplantable in the immunologically competent mouse.

In the AL/N mouse strain an SV40 transformed cell line SV AL/N, even after very large number (~275) of t.c.t. and at 10⁸ cell dose is rejected by the immunologically competent adult mice⁸. The recognition and rejection is due to SV40 specific surface and transplantation antigens^{9,10}. In irradiated mice tumours can be caused by injecting 10⁷ SV AL/N cells. The tumour cells re-established in culture retain SV40-specific nuclear (T) and cell surface antigens¹¹, and have increased tumorigenicity: 10⁴–10⁵ cells induce tumour in the immunologically competent mouse⁸.

Fig. 1 Cell genealogy and cloning. The box indicates the SV40-positive cell lines. Above the horizontal lines are the mass cell lines. For cloning the T AL/N cells at t.c.t. 68 were well dispersed by trypsinisation, and 0.2 ml diluted aliquots in growth medium (reinforced Eagles with doubled amino acid and vitamins, with added antibiotics and 10% foetal calf serum) containing on the averages 0.4 cells were put into each of the 96 wells of a Falcon microtests plate. Each well was surveyed daily, and clones were picked only from wells in which there was only one cell at the onset, and the cell growth was from one focus. A single clonal line T AL/N C1 3 was selected. For infection 2.5×10^5 T AL/N clone 3 cells were exposed in 1 ml Eagles medium for 1 h at 37°C in a shaking water bath to 9×10^7 plaque forming units (PFU) SV40, small plaque forming strain 776. This ratio of PFU per cell (360) was chosen to obtain 30%–50% T antigen positive cells at 2 d after infection. The cells were then placed in growth medium in a 10-cm Falcon Petri dish and cultivated as before¹². After t.c.t. at 5 d into two dishes and a total of 10 d growth, there were $\sim 10^7$ cells, of which 30%–40% were T-antigen positive (T antigen tests by nuclear fluorescence were carried out as previously⁸ on separate aliquots). At this time the cells were recloned using the method described above. Five subclones, each clearly grown up from one cell, were obtained. Substantially all (> 95%) of the cells of the subclones designated 1 and 2 were strongly T antigen positive when tested repeatedly up to > 200 t.c.t., while all of the cells of the subclones 5, 6, 8 were T antigen negative. Arrows with broken line indicate the origin of the T-antigen negative (revertant) tumour cell lines.

From the same AL/N cell line from which the SV AL/N cells were obtained, a highly tumorigenic spontaneously transformed T AL/N cell appeared during tissue culture. After 40 t.c.t. 10^3 T AL/N cells gave progressively growing and lethal fibrosarcomas when injected intramuscularly or subcutaneously into the adult immunologically competent syngeneic mouse^{8,9,12}.

What would happen to the tumorigenicity of the T AL/N cells if they were infected and transformed also by SV40? The SV40 induced cell surface and transplantation antigens were expected to facilitate rejection in the syngeneic mouse, opposing the tumorigenicity of the T AL/N cells. This system allowed us to embark on a novel study on the balance between strong cellular tumorigenicity and a superimposed strong and well characterisable (SV40 specific) antigenic property.

Transformation by SV40 is an inefficient process, since

only a minor fraction of the infected cells have stable insertion and thus expression of SV40 DNA. The SV40 may infect and transform cells selectively which have greater, or lower tumorigenicity. To avoid such selection we first cloned the T AL/N cells. The resulting cells, T AL/N clone 3 had retained the high tumorigenicity. After infection by SV40 of the T AL/N clone 3 cells, both T antigen-positive and negative subclones were obtained and characterised (see Fig. 1). The SV40 T antigen positive subclones were about 100-fold less tumorigenic than the T antigen-negative sister subclones or the parent T AL/N clone 3 cells. When the tumours from the T antigen positive subclones were re-established in culture, we found that SV40 T, surface and transplantation antigen negative (revertant) tumour cells resulted.

We describe here the conditions when such *in vivo* selection reproducibly occurs, prove that the revertant tumour cells are true progenies of an SV40 transformed cell, and also describe some of the phenotypic properties of the various cells. We also show that the ability of cells to grow without anchorage in a viscous medium is not a general correlate of tumorigenicity in the syngeneic mouse.

AL/N mouse cell clones

The genealogy and certain properties of the cell lines are summarised in Fig. 1 and Table 1. The AL/N mouse

Fig. 2 Presence of SV40-specific surface antigen in the T antigen-positive cells. % Chromium release represents residual cytotoxicity of an antiserum prepared in the syngeneic mouse against SV AL/N cells after the absorption by the different cells. ●, Control (no cells were used for absorption); △, absorption by T AL/N clone 3 cells; □, absorption by the T antigen-negative subclone 5 cells; ○, absorption by the T antigen-positive subclone 1 cells. Similarly, there was no significant absorption by the cells of the T antigen negative subclone 6, but almost complete absorption of the cytotoxicity by cells of the T antigen-positive subclone 2 (data not shown). For absorption 10^6 cells were plated into 60-mm Falcon plastic tissue culture Petri dishes. After 24 h growth the near confluent cell layer ($\sim 2 \times 10^6$ cells) was washed twice with the growth medium, and 400- μl aliquots of antisera (diluted 1:200 with growth medium) were incubated (30 min, 37°C) sequentially with three such dishes containing 2×10^6 cells. The absorbed antisera were centrifuged at 500g for 5 min, and further dilutions were tested for residual cytotoxicity on SV AL/N target cells, by a method described before^{18,19}.

Table 1 Summary of the biological properties of the cell lines

Cell line	SV40 T antigen	Tumorigenicity TD ₅₀ * (Cells per mouse)	Time to death† (weeks)	Tissue culture growth property Saturation‡ density (cells cm ⁻² × 10 ⁵)	Colony formation in viscous Methocell suspension‡ (%)
T AL/N mass line	—	< 10 ²	9	5.5	2
T AL/N clone 3	—	10 ^{1.7}	14	3.0	0.007
SV40 infected					
Subclone 1	+	10 ^{3.8}	13	1.0§	20
2	+	10 ^{3.9}	14	0.6§	10
5	—	10 ^{1.5}	17	2.4	< 0.0001
6	—	< 10 ¹	21	3.5	0.06
8	—	10 ^{2.5}	16	3.1	0.03
SV AL/N mass line	+	> 10 ⁸	—	5.3	10

*Tumorigenicity was tested by intramuscular (i.m.) injection of cells at least in three dilutions each differing 10-fold, into groups of 6–8-week-old AL/N mice, 10 mice in each group. TD₅₀ is the cell dose which caused in 50% of the animals large (min. 1 cm Ø), and eventually lethal, tumours. It was calculated as follows: $TD = 10^{d+x}$, where d is the (\log_{10}) number of cells which caused tumour in just below 50% of the mice, and $x = (a-50)/(a-b)$ where a is the % of mice with tumours within that group of 10 mice which had nearest to but above 50% tumours, and where b is the % nearest to but below 50%. The TD₅₀ values were reproducible within $\pm 0.5 \log_{10}$ at 10² cell dose, and $\pm 0.2 \log_{10}$ at 10⁴ cell dose.

†Time when substantially all the animals, injected (i.m.) with a cell dose rounded up to the nearest integer of the exponential of TD₅₀, die off due to progressive tumour growth. There were no regressing tumours.

‡Determined in the presence of 10% foetal calf serum⁸.

§Cells after reaching confluency tend to detach from the substratum.

embryo cell line—parent line to all AL/N cells reported here—at t.c.t. 28 had a median tumour cell dose, TD₅₀ of 10³–10⁵ (ref. 12); and at t.c.t. 40, TD₅₀ < 10² (ref. 8). This T AL/N cell was characterised again at 65 t.c.t. (Table 1), and cloned as described in the legend to Fig. 1.

The SV AL/N cells were rejected. The spontaneously transformed T AL/N cells and the derivative T AL/N C1 3 cells were strongly tumorigenic (TD₅₀ ~ 10³), as were the SV40 T antigen-negative subclones 5, 6, and 9. But, the T antigen-positive subclones 1 and 2 were about 100 fold less tumorigenic (TD₅₀ ~ 10⁴), than the parent T AL/N C1 3 cells, or the sister subclones 5, 6, and 8 (Table 1).

The SV40 T, transplanted, and cell surface antigens probably represent modifications of products of the same SV40 cistron^{14,15}. The antigens co-purify^{10,14}, and mutants in *tsA* coordinately affect expression of all three antigens¹³. Experiment 1 in Table 2 suggests the presence of SV40 specific transplanted antigen(s) in whole subclone 1 and 2 cells; this then may be the cause of the reduced tumorigenicity of these cells. Experiments 2 and 3 in Table 2 demonstrate the presence of SV40-specific transplanted antigens in extracts of subclone 1 cells, but the absence in extracts of the T antigen-negative cells, such as subclone 5, T AL/N clone 3 cells, and a tumour cell line (number 124) obtained from subclone 1 cells (see below). Similarly, SV40-specific surface antigen was shown to be present in the T antigen-positive cells, but not in the corresponding T antigen-negative cells, when tested by an SV40-specific serum mediated cytotoxicity microassay (Fig. 2).

Cells of both of the SV40 antigen-positive subclones 1 and 2 carry in a rescuable form²⁰ the SV40 virus used for the transformation: by co-cultivation with permissive (CV-1 monkey) cells and fusion with ultraviolet light-inactivated Sendai virus, from the heterokaryons formed, infectious SV40 small plaque-forming virus was recovered: 7×10^6 plaque-forming units (PFU) per ml from subclone 1, 2×10^5 PFU per ml from subclone 2.

Tumour cell lines

Tumours were induced repeatedly by injecting 10⁴ or 10⁵ cells of subclones 1 and 2, into the hind leg of syngeneic adult AL/N mice, and from the tumours cell lines were established as before⁸. Chronologically at first, four tumour cell lines were obtained: first tumour line from 10⁴ subclone 1 cells at t.c.t. 17 (after the SV40 infection) designated cell

line 113; second from 10⁵ subclone 1 cells at t.c.t. 25; third from 10⁴ subclone 2 cells at t.c.t. 21; fourth from 10⁵ subclone 2 at t.c.t. 22. All four tumours were hard, encapsulated, and were identified histopathologically as fibrosarcomas, similar⁸ to those induced by the T AL/N or the T AL/N C1 3 cells. All cells from all four tumours were found completely devoid of SV40 T antigen by the nuclear immunofluorescence test⁸ in primary culture, or after additional and prolonged culturing (>30 t.c.t.). The SV40 T antigen-positive cells apparently were rejected by the immunologically competent mice, and tumours grow up only from SV40 T antigen-negative cells.

Nude mice—congenitally athymic thus deficient in thymus-dependent immunity—would not be expected to reject the SV40 T, surface and transplanted antigen-positive cells. To test this, *nude* mice (random +/nu × nu/nu, from NIH Laboratory Animal Genetic Center) were injected with 2×10^5 subclone 1 cells, and tumours were obtained within 4 weeks in most animals (11 of 14 mice). Cells of these tumours (4 tested) were all positive for SV40 T antigen by both nuclear fluorescence and the quantitative complement fixation test, both in

Fig. 3 Tests for SV40-specific surface antigen in various cell lines. The % cell lysis is the same as % chromium release in Fig. 2, and represent residual cytotoxicity against the SV AL/N target cells, after absorption by the various cell lines. Control (no cells used for absorption): —▽—; absorption by subclone 5 cells: —□—; absorption by subclone 1 tumour cells from a syngeneic mouse (cell line 113): —△—; absorption by subclone 1 cells: —○—; absorption by subclone 1 tumour cell from a nude mouse: —□—. Absorption and assay conditions as in Fig. 2.

Table 2 Tests for SV40-specific transplantation antigens

Immunisation		Challenge		Tumour	<i>P</i>
Cell or extract	Dose number or mg	Cell type	Number	death/inoculated	
Experiment 1					
Subclone 1 cell	10 ³ (×4)	'M' SV AL/N T ²	10 ⁴	0/10	<0.05
	10 ³ (×4)		10 ⁵	0/10	<0.05

Control	—		10 ⁴	8/8	

In experiment 1 syngeneic AL/N mice were immunised by i.m. injection ×4 weekly apart (into right hind leg) of the given number of subclone 1 or 2 cells. These mice were challenged 1 week after the last immunisation by SV40-positive tumorigenic cells 'M' SV AL/N T², obtained and characterised previously⁸, by injection into their left hind leg. The number of progressively growing tumours in the left hind leg is given. In experiments 2a and b BALB/c mice were immunised by extracts (mg protein) of the various cells obtained with 0.5% Triton X-100 (refs 10, 16). The mice were challenged by an SV40-transformed BALB/c mouse kidney cell mKSA (ref. 3) which after repeated transplantation in the BALB/c mice⁹ was established in ascites form: mKSA-ASC¹⁷; it was shown before that cells in both forms contain SV40-specific transplantation antigen^{3,17}. For specificity control the challenge was by a chemically transformed Meth A BALB/c mouse embryo cell. Tumour deaths occurred by ascites or by fibrosarcoma at the site of challenge after about 1 month, groups were observed for 3 months. Experiment 3 shows the absence of SV40-specific transplantation antigen in the extract of tumour cells 124 (see text); these experiments were done similar to, and simultaneously with experiment 2. Control mice were injected with TBS. P values were calculated as before¹⁴; NS, not significant.

primary culture and also after various numbers (~10) of tissue culture transfers.

When tested for SV40-specific surface antigen, all tumour cell lines obtained from the syngeneic animals were devoid, but the tumour cells from the nude mice possessed this surface antigen. Examples, with controls, are given in Fig. 3; clearly, subclone 1 tumour cells (compare line 113) do not possess SV40-specific surface antigen. The subclone 1 tumour cell lines (for example 124, see below) were devoid of SV40-specific transplantation antigen (Table 2, experiment 3).

There are two possibilities to explain the *in vivo* selection of SV40 antigen negative tumour cells. The first possibility is that a T antigen-positive subclone, say subclone 1, is not a true subclone, but is consistently contaminated with a low number of (about 10⁻²) of untransformed T AL/N clone 3 cells (which cannot be detected even by the T antigen nuclear staining) and which can grow out as tumours; while the majority of the cells which are the SV40-specific T, surface and transplantation antigen-positive cells are all rejected by the immunocompetent mouse. The second possibility is that subclone 1 was indeed a good clone, free of T AL/N clone 3 cells, but a certain small (~1–0.1%) fraction or number of subclone 1 cells loses (the ability to express) SV40 antigens, and these revertant cells are then selected out to grow as tumours, while the SV40 T, surface, and transplantation antigen-positive cells, which are in great (about 10²–10³) excess, are all rejected.

Recloning of subclone 1 cells gave only T antigen-positive cells (six reclones tested). Co-cultivation experiments of known number of subclone 1 and T AL/N clone 3 cells

indicated no preferential growth of subclone 1 cells (data not shown). Both of these made it unlikely that subclone 1 had originated from the two type of cells. It took, however, a fortunate finding of characteristic marker chromosome translocation to virtually eliminate the first possibility. When chromosomes were banded from subclone 1 cells and from the derivative tumour cells 113, three common marker chromosomes, number 1, 2 and 3 in Fig. 4, were found clearly in each metaphase of these two cell lines. Metaphases were chosen at random and 17 metaphases from subclone 1, and 14 metaphases in the resulting tumour cells 113 were compared. However, when banding the T AL/N clone 3 cells (at t.c.t. 21, chromosome modality 38), in 20 randomly chosen metaphases none was found to possess the easily identifiable chromosomal marker 1, but clearly all were found to possess the easily identifiable chromosomal markers (classified as Robertsonian translocations) proving that the subclone 1 cells but not the T AL/N clone 3 cells are the direct parents of the tumour cells.

Being assured that subclone 1 is indeed a true clone, we used the subclone 1 cells to check the reproducibility of selecting SV40 antigen negative tumour cell lines by *in vivo* passage through the immunologically competent syngeneic mouse. At t.c.t. 12, 10⁴ subclone 1 cells repeatedly induced T and surface antigen negative tumour cell lines (see Table 3, tumour cell lines 127 and 128), as did 10⁵ subclone 1 cells (cell line 124). Six cloned lines were obtained from tumour cell line 124, these were designated as cell lines 129–134, and all were found to be T antigen negative. The tumorigenicity of tumour cells 124 was high (TD₅₀ = 10³), similar to other T antigen negative cells;

however, its clonal derivatives 129–134 had various TD_{50} values between 10^2 and $>10^4$, indicating that cloning may select for differences in tumorigenicity. These and other phenotypic data are summarised in Table 3.

Thus, the true clonal subclone 1 cells give reproducibly SV40 antigen negative tumours when passed through the immunologically competent mice. These tumours can be obtained after injection of as few as 10^4 or 10^5 cells. The tumour cells can possess high tumorigenicity ($TD_{50} \sim 10^2$) and the resulting fibrosarcomas never regress: the tumour cells in this respect are similar to the T AL/N C1 3 parent cells or to the T antigen-negative sister subclones. Apparently subclone 1 cells are prone to revert or segregate at a high frequency to a stably SV40 antigen negative cell line. Current studies by DNA reassociation kinetics indicate that subclone 1 cells contain approximately 1 genome equivalent of SV40 DNA, while the tumour lines or tumour clones tested contain about 0.5 copies per diploid complement of DNA which seem to be depleted in some of the early half of the SV40 genome, and which are not transcribed to RNA. These observations (J.M.K., P.T.M., M. Brown and G. Khoury, in the press) are consistent with the biological and chromosome findings.

The tumorigenicity in the syngeneic host of the cell lines investigated does not correlate with anchorage-dependent growth in viscous medium. There were highly tumorigenic cells with negligible or no observable growth in

Fig. 4 Marker chromosomes. Partial karyotypes of four subclone 1 cells (banded at t.c.t. 22) and four resulting tumour cell 113 metaphases (banded after 12 t.c.t. following the re-establishment) are compared pairwise in rows a, b, c, d. The three marker chromosomes present in these cells are arranged columns 1, 2 and 3. Chromosome(s) from the subclone 1 cells appear in left side of the columns. Chromosome(s) from the resulting tumour cells 113 appear in right side of column. Slides were stained with quinacrine-mustard for Q banding²¹, and photographed with a Zeiss photomicroscope III equipped for epi-fluorescent microscopy. After photomicrographic enlargements of the chromosomes, karyotypes were numbered and arranged according to size²². The subclone 1 cells were essential sub-diploid (chromosome modality 36) at t.c.t. 16, but some cells became polyploid when banded (t.c.t. 22) which explains why some of the marker chromosomes are present more than once. Tumour cells 113 were essentially sub-diploid (chromosome modality 33) at t.c.t. 8 and 12.

Table 3 Properties of the subclone 1 tumour cells and of clones of tumour line 124

Tumour cell line	Tumorigenicity (TD_{50})	Colony formation in viscous Methocell suspension (%)
113	NT	10
124	10^2	0.18
127	NT	0
128	NT	0.01
Clones of 124		
129	10^2	0.01
130	10^2	0.28
131	10^3	0
132	$>10^4$	1.5
133	10^3	0.12
134	$>10^4$	0

All tumour cells were SV40 T and surface antigen negative; all the clones of 124 were tested only for SV40 T antigen, they were all negative. The tumour line 124 was cloned by a single cell technique. Tumorigenicity and colony formation in viscous Methocell were determined as in Table 1. NT, not tested.

Methocell (see Tables 1, 5). We have similar observations on other BALB/c and AL/N highly tumorigenic cloned cells (data not shown). Neither did the presence and functioning of the SV40 early gene correlated absolutely with anchorage-independent growth: the tumour cell line 113 is SV40 antigen negative, but grows about as well in Methocell as the SV40 antigen-positive subclones 1 and 2. A recent publication appeared with partially contrasting claims in other less well matched cell systems²³.

The above experiments open up new kinds of genetic, immunochemical and biochemical studies using the strong *in vivo* antigen activity endowed to a mammalian tumour cell by transformation with SV40 to cause rejection. It also gives a novel perspective on biological consequences of SV40 transformation of cells, probably in the majority of the mammalian species. We emphasise, however, that the above experiments show that SV40 endows immunogenicity to, and allows recognition and rejection of, only those tumorigenic cells which were transformed by SV40, and may not alter the tumour-specific transplantation antigen associated with the spontaneously occurring or otherwise induced malignant transformation.

We thank Miss Cecily Sun for chromosomal banding, Drs O. J. and D. A. Miller for review of the marker chromosomes, and Dr L. W. Law for the ascites cell line.

Note added in proof: The revertant tumour cells (cf. clone 130) can be re-transformed by SV40, and on transplantation of a T antigen-positive clone T antigen-negative revertant tumour cell line can be obtained again.

letters to nature

Upper limits for the radio pulse emission rate from exploding black holes

IT has been suggested¹ that the explosion of a primordial black hole (pbh) might produce a coherent radio pulse detectable at a distance of $\sim 10^4$ pc with a simple antenna. Several searches²⁻⁵ for radio pulses arriving from random directions in space, such as might be produced by supernovae⁵⁻⁷, have already been carried out using wide beam (all-sky) antennas, and the negative results obtained are used here to place limits on the pbh radio pulse emission rate per unit volume. An indication has already been given⁸ of the limits which some previous radio searches impose, and of the influence of antenna aperture and beamwidth on achievable limits. This paper presents a more general analysis of limit criteria, including consideration of the effects on the pulse timescale of the interstellar medium, and examines the factors which determine the optimum search strategy for pbh radio pulses. It is reported that the best radio limit⁴ known to the author, could be improved by at least times 10^6 using existing techniques. In addition, examination of this existing limit⁴ shows that it is already ~ 80 times better (99.5% confidence level) than a limit which it has been suggested⁸ might be attainable in the optical region, and is $\sim 10^6$ times better than pbh explosion rate limits obtained from γ -ray observations^{9,10}, although the γ -ray limits do not involve the generation of a coherent electromagnetic pulse.

We assume that the pbh's are concentrated in galactic haloes (radii ≈ 20 kpc)⁹ and that the pulse energy, E_t , in J (ref. 1) is given by

$$E_t \approx 1.5 \times 10^{28} \nu^{-0.33} \quad (1)$$

where ν is the characteristic frequency (Hz) of emission. The value of the characteristic frequency is highly uncertain¹, and so the situation is considered where ν is equal to the frequency of observation. The attainable limit, L (volume⁻³ time⁻¹), established by a negative search at the 99.5% confidence level is given by

$$L \approx 5 (VS)^{-1} \quad (2)$$

where S is the duration of the search. V , the volume of space observed above the threshold sensitivity, is given by

$$V \approx (\Omega/3) R_M^3 \quad (3)$$

where Ω is the antenna beam solid angle and R_M is the maximum distance at which detection is possible. We adopt a detection threshold of 5σ signal-to-noise ratio and examine the factors which determine R_M . For an antenna of gain g (relative to an isotropic radiator), and receiver bandwidth $\Delta\nu$, the pulse energy collected (E_{col}) is at least

$$E_{\text{col}} \approx \frac{1}{4} (E_t/4\pi R_M^2) (\Delta\nu/\nu) (gc^2/4\pi\nu^2) \quad (4)$$

$$= 2 \times 10^{42} \nu^{-3.33} \Delta\nu R_M^{-2} g \quad \text{J} \quad (5)$$

where c is the velocity of light and R_M is in metres. (The factor of $\frac{1}{4}$ allows for the source being up to -3 dB away from the beam axis ($\frac{1}{2}$) and for only one polarisation being observed ($\frac{1}{2}$)).

The minimum pulse energy, E_{min} , which the radiometer can detect, is

$$E_{\text{min}} \approx 5kT(\Delta\nu\tau)^{0.5} \quad (6)$$

(where k is Boltzmann's constant, T is the system temperature, and τ is the integration time), provided that the pulse duration at the integrator input, $t_p \leq \tau$. The intrinsic timescale of the pulse is $\sim 1/\nu$ (ref. 1), so that t_p is principally determined by the radiometer response time $\approx 1/\Delta\nu$, by interstellar dispersion broadening over the band $\Delta\nu$, and by interstellar scattering. If $\Delta\nu$ is gradually increased, the signal-to-noise ratio will improve until the pulse time scale is dominated by dispersion. Once this stage is reached ($\Delta\nu \approx 10^4 - 10^5$ Hz for typical dispersion measures) little further improvement in signal-to-noise ratio is obtainable by further increase in $\Delta\nu$ (see equation (9) below), unless de-dispersion is used. The timescale, t_p , in s due to dispersion is given by

$$t_D = 2.8 \times 10^{-7} \nu^{-3} \Delta\nu DM \quad (7)$$

where DM is the dispersion measure in m^{-2} . Setting $t = t_D = \tau$ in equation (6) above gives

$$E_{\text{min}} \approx 4 \times 10^{-26} T \nu^{-1.5} \Delta\nu (DM)^{0.5} \quad \text{J} \quad (8)$$

where T is in Kelvins. Equating E_{col} and E_{min} , gives

$$R_M \approx 8 \times 10^{33} \nu^{-0.92} T^{-0.5} g^{0.5} (DM)^{-0.25} \quad \text{m} \quad (9)$$

$\Delta\nu$ has been eliminated from this expression.

In general, the system temperature, T , is a function of both sky noise and receiver noise. To minimise T (and DM), observations should be directed towards the regions of the galactic poles, where (for the north galactic pole (NGP)) the sky temperature, T_{sky} , is given by¹¹⁻¹³

$$T_{\text{sky}} \approx 2 \times 10^{24} \nu^{-2.7} \quad (10)$$

This gives $T_{\text{sky}} \approx 80$ K at 200 MHz. Above this frequency, receiver noise will begin to dominate the system noise, so that further increase in ν will tend to reduce sensitivity. Therefore, for observations near the NGP at $\nu \approx 200$ MHz with a sky noise limited system, equation (9) becomes

$$R_M \approx 5 \times 10^{21} \nu^{0.43} g^{0.5} (DM)^{-0.25} \quad (11)$$

To estimate DM , a model is adopted¹⁴ in which the electron distribution is uniformly stratified parallel to the galactic plane and has an exponential distribution perpendicular to the plane

with a scale height of 600 pc (refs 14, 15) and a density at the plane of $3.3 \times 10^4 \text{ m}^{-3}$. Thus, DM is given in m^{-2} by

$$DM \simeq 6 \times 10^{23} (1 - \exp(-R_M \sin b / 1.8 \times 10^{19})) / \sin b \quad (12)$$

where b is the galactic latitude. If $g \geq 10$, the antenna beam limits (-3 dB) will be less than 30° from the NGP so that to a good approximation, $\sin b \simeq 1$. For $g = 10$ (a small, simple antenna) and $\nu = 200 \text{ MHz}$, equations (11) and (12) give $R_M \simeq 2.2 \text{ kpc}$. Putting the expression for R_M given by equation (11) into equation (3) gives as the volume of space observed

$$V \simeq 7 \times 10^{65} \nu^{1.3} g^{0.5} (DM)^{-0.75} \text{ m}^3 \quad (13)$$

which, for $g = 10$ and $\nu = 200 \text{ MHz}$, is $6 \times 10^9 \text{ pc}^3$. Thus, observation for one year (assuming no pulses were detected) could yield a 99.5% confidence limit of $\sim 10^{-9} \text{ pc}^{-3} \text{ yr}^{-1}$. Use of an antenna 10 times larger in diameter ($\sim 15 \text{ m}$ at 200 MHz) for the same observation period might improve this limit 10-fold and would observe to the edge of the halo. The long observation times required for further limit improvement may rule out the use of still larger antennas. An Arecibo-type antenna, however, using existing de-dispersion facilities might just reach out to $\sim 700 \text{ kpc}$ in the approximate direction of the NGP, but to be worthwhile, the increased volume would have to contain an external galaxy. A more effective way of improving the limit would be to use a multiply-phased array. A 10×10 element array at 200 MHz could observe to the halo edge, and still maintain a $\sim 1\text{-sr}$ solid angle, thereby offering a potential 1,000-fold increase in the volume of space observed, relative to a single element ($g = 10$), and so attain a limit of $\sim 10^{-12} \text{ pc}^{-3} \text{ yr}^{-1}$ in 1 yr observation.

The above results for R_M and V are obtained assuming a rather idealised situation in which the characteristic emission frequency is $200 \text{ MHz} \simeq$ observation frequency, and observations directed towards the NGP are carried out with a sky noise limited system and correctly optimised integration time. For this situation, and with $g \geq 10$, $R_M \geq 4 \times$ scale height of the electron distribution, so that to a good approximation DM is independent of R_M and from equation (13)

$$V \propto g^{0.5} \quad (14)$$

Previous all-sky searches, however, included observations both near to and far from the NGP, and were generally not sky noise limited and did not have optimised integration times. The effect was that these searches were usually confined within the galactic plasma, so that DM was no longer approximately independent of R_M (equation (12)) and the proportionality in equation (14) was not necessarily valid. For any particular search

$$R_M = (E_t / (4\pi W \nu t_p))^{0.5} \quad (15)$$

where W is the search flux threshold per unit bandwidth, and the output pulse timescale, t_p , is determined by the dispersion, scattering, bandwidth and integration time which the pulse encounters. In all previous searches, $t_p \simeq t_D$, so that when $\tau \gg t_p$, $t_p \simeq \tau$, and putting the expression for R_M given by equation (15) into equation (3) shows that proportionality (14) is applicable in this case. When $\tau \leq t_D$, V must be obtained, however, by solving equations (12) and (15) for R_M and then substituting the expression obtained into equation (3). The result is that when $\tau \leq t_D$, V is a weaker function of g than it is in equation (14) and in the extreme case where approximately $DM \propto R_M$ (for example, when observing

along the galactic plane) and $\tau \ll t_D$, V is independent of g . Thus, it is important to observe well out of the galactic plane and have $\tau \simeq t_D$.

Table 1 gives the best pbh radio pulse rate limits I know (99.5% confidence level) within the frequency decades 10–100 MHz, 100 MHz–1 GHz, and 1–10 GHz, and the actual frequencies at which they were obtained. In each case, it is assumed that the characteristic emission frequency equals the observation frequency. Also shown are the corresponding values of R_M for each

Table 1 Primordial black hole radio pulse rate limits

Reference	Frequency range (MHz)	Rate limit ($\text{pc}^{-3} \text{ yr}^{-1}$)	Frequency (MHz)	Distance, R_M (pc)
*	10–100	1.5×10^{-6}	45	370
4	100–1,000	5×10^{-7}	270	975
5	1,000–10,000	4×10^{-5}	1,400	525

* Unpublished observations at 45 MHz, December 1970 to March 1971, carried out by R. W. P. Drever and W. P. S. Meikle (Glasgow), G. A. Baird, T. Delaney and B. G. Lawless (Dublin), R. A. Porter and R. E. Spencer (Jodrell Bank).

search. The searches at 45 MHz and 1.4 GHz had $\tau < t_D$, and the 270-MHz search had $\tau > t_D$. These limits are 10^4 – 10^6 times better than the pbh explosion rate limits achieved from γ -ray studies^{9,10}.

I thank Professor R. W. P. Drever for many valuable comments and suggestions, and also Professor S. A. Colgate, Dr J. Hough and Dr R. D. Joseph for helpful discussions.

Neutrino-induced nucleosynthesis and deuterium

DOMOGATSKY and Nadyozhin¹ have suggested that the neutrino flux from a collapsing stellar core might induce nuclear transformation in the mantle and envelope of the surrounding pre-supernova star. They further suggest that such weak interactions might be responsible for producing the so called 'p-process' nuclei which are the rare heavy elements bypassed by the neutron capture chains responsible for synthesising most nuclei heavier than iron. This letter points out a weakness in their model as a mechanism for p-nucleosynthesis and concurrently suggests a rather novel method for the synthesis of deuterium that may have been operative during an early generation of supermassive stars ($M \sim 10^6$ – $10^8 M_\odot$).

First, consider the conditions requisite for producing p-process nuclei from the more abundant neighbouring r- and s-process isotopes (see ref. 2 for an explanation of this nomenclature).

One might invoke the charged-current processes suggested by Domogatsky and Nadozhin for producing the nucleus (A, Z)

where $(A+1, Z)^*$ is a neutron unbound state of the nucleus having atomic mass $A+1$ and Z protons or by

In addition to the charged-current processes that they suggest, one might also add the neutral current process

and others that come to mind. The cross section, however, for each of these processes is very small, Domogatsky and Nadozhin estimate a value $\sigma_\nu \sim 10^{-41} \text{ cm}^2$ as typical. According to Cameron³ the relative abundance of p -nuclei to neighbouring nuclei produced by neutron capture is about 1%. Therefore, the production factor

$$P = \phi_\nu \sigma_\nu \gtrsim 0.01 \quad (4)$$

where

$$\phi_\nu = \frac{E_{\nu(\text{tot})}}{4\pi R^2 E_\nu} \quad (5)$$

R is the radius from the collapsing, neutrino-emitting core to the mass shell where the neutrino-induced nucleosynthesis occurs, and E_ν is the mean energy of the emitted neutrinos. An upper bound to the total energy emitted in neutrinos is the binding energy of a typical neutron star, 10^{53} erg . Actually a smaller number, say 10^{52} erg , is probably more appropriate⁴. Using $E_\nu = 10^{52} \text{ erg}$ and $E_\nu = 15 \text{ MeV}$ one finds from equation (4) that $R \lesssim 2 \times 10^8 \text{ cm}$.

Problems arise when the conditions extant at $R = 2 \times 10^8 \text{ cm}$ in a realistic pre-supernova star^{5,6,7} are examined. For most massive pre-supernova stars of interest (say $M \gtrsim 15 M_\odot$) this region lies interior to the neon burning shell and probably interior to the oxygen burning shell and is characterised by temperatures in excess of $2 \times 10^9 \text{ K}$. At such high temperatures, all heavy seed nuclei will be rapidly photodisintegrated to iron-group nuclei. It can be estimated, using rates given by Woosley and Howard⁸, that at $T = 2 \times 10^9 \text{ K}$ all seed nuclei heavier than $A = 150$ will be destroyed by photodisintegration reactions in a time of only a few thousand seconds. This is considerably less than the time occupied by oxygen and silicon burning in the core of the star, hence seed nuclei with $A \geq 150$ are not present at $R = 2 \times 10^8 \text{ cm}$ when the star blows up. Actually the problem is even more severe than so far described. The number 0.01 used in equation (4) is applicable only if all the r - and s -process nuclei ever produced have been exposed to precisely the conditions described. Since in reality the fraction of seed nuclei so exposed has been very small the required production ratio must be correspondingly larger, $P = 0.1$, for example, if only

10% has been irradiated. Thus the required exposure radius is smaller, the temperature higher, and the likelihood of seed survival smaller. The p -process nuclei can, on the other hand, be produced by more traditional strong and electromagnetic processes that occur farther out in the star as has been recently shown by Woosley and Howard⁸.

Consider now another possibility for neutrino-induced nucleosynthesis. The reaction

can produce a neutron flux in the hydrogen envelope surrounding a strong anti-neutrino source. It is important to note that anti-neutrinos are required for this process. Neutrinos, as result from electron capture and positron decay, for example, will not work. If the density of the hydrogen exceeds roughly

$$\gtrsim 10^{-8} \left(\frac{1 \text{ mb}}{\sigma_{n\gamma}} \right) \left(\frac{10^8 \text{ cm s}^{-1}}{v_T} \right) \text{ g cm}^{-3} \quad (7)$$

these neutrons will be captured before decaying. Here v_T is the mean velocity of the neutron and $\sigma_{n\gamma}$ is the radiative capture cross section in millibarns. It is assumed here that inelastic scattering will reduce the neutron energy to some relatively low value ($\sim \text{keV}$) before capture occurs. Even though heavy elements such as ^{56}Fe have substantially larger neutron capture cross sections than hydrogen it is assumed that the numerical preponderance of H-nuclei will make them more likely candidates for capturing the neutrons produced by equation (6). Thus deuterium is formed by

The viability of this mechanism for deuterium production depends upon (1) the existence of a sufficient anti-neutrino flux to produce D/H of at least 2×10^{-5} (ref. 9), the currently accepted interstellar value, and (2) the material irradiated being cool enough so that the deuterium formed is not destroyed by ${}^2\text{D}(p, \gamma){}^3\text{He}$ before ejection. First I shall show that supernova probably cannot satisfy these requirements.

The anti-neutrino flux from a supernova explosion is thermally produced and is not as large as the neutrino flux which receives a big contribution from electron capture. Assume the collapsing core emits 10^{52} erg of 15 MeV anti-neutrinos (this would be an upper bound). The cross section for the process in equation (6) at $E_\nu = 15 \text{ MeV}$ can be calculated¹⁰ to be roughly $2 \times 10^{-41} \text{ cm}^2$. From equations (4) and (5) the production ratio at a radius R will then be

$$P = 7 \times 10^{-6} (10^{10} \text{ cm}/R)^2$$

Since the radius of the hydrogen burning shell in a highly evolved massive star⁷ exceeds $2 \times 10^{10} \text{ cm}$ one cannot produce sufficient quantities of deuterium to account for present abundance determinations. This argument is strengthened by the fact that the hydrogen temperature does not drop below 10^7 K until $R \gtrsim 10^{11} \text{ cm}$ thus deuterium formed interior to this radius would be destroyed in less than 1,000 s (ref. 11) (less than the speed of sound communication time to the core).

I will end this letter, however, with a speculation on a site where equation (6) might function with greater efficiency. Some models for active galactic nuclei and quasars suggest the existence early in a galaxy's lifetime of supermassive stars and/or black holes¹². The explosion of a $10^8 M_\odot$ star might produce 10^{60} erg (ref. 13). The formation of a $10^6 M_\odot$ black hole would emit a similar quantity of

energy. If the collapse of these objects produces matter at very high temperature ($T \gtrsim 10^{10}$ K) a substantial fraction of this energy might be emitted as anti-neutrinos. If one takes 10^{59} erg, $E_\nu = 15$ MeV, and $R = 10^{12}$ cm, for example, a production ratio $D/H \sim 7 \times 10^{-3}$ could be attained. Even if a small fraction of all the hydrogen in a galaxy were processed through these conditions the present abundance of deuterium could be understood.

Support for the astronomical theory of climatic change

AMONG recent papers supporting the astronomical theory of climatic change¹⁻⁵, the work of Hays *et al.*⁵ is of particular importance in providing detailed quasi-periods from deep-sea cores. I wish to draw attention here to the fact that the periods found are very close to the periods predicted by Berger^{6,7} in the latest and most accurate calculation of the variations of the various 'Milankovitch' parameters. The roughly 24,000- and 19,500-yr periods from the core samples are not significantly different from the periods associated with the largest amplitude terms in the series expansion of the precessional parameter $e \sin \tilde{\omega}$; the periods around 42,000 yr are essentially identical with the most important term in the expansion of the obliquity ε ; and the peaks in the range of 106,000 yr containing most of the variance, might be regarded as either a contribution from the eccentricity, where a weighted mean of the main amplitude terms has a period of 110,753 yr, or as a beat effect of precessional periods, as has been noted by Wigley⁸.

The astronomical theory of climatic change, originating from Croll⁹ and developed by Milankovitch¹⁰ has been widely discussed and needs no elaboration here. To establish the validity of

that theory, the following three criteria must be met. (1) Are the quasi-periodicities of the Earth's orbital elements significantly present in the geological record?¹¹ (2) Is there any significant correlation between insolation curves and geological data?¹² (3) Can these insolation changes be correlated with climatic changes^{13,14}?

I have previously^{6,7} demonstrated the accuracy of a new astronomical solution for the long-term variations of the Earth's orbital elements. From theoretical formulae given in refs 6 and 7 it is possible to write, in an easily applicable form, the series expansion of astronomical elements required in the computation of the insolation, that is, the eccentricity e of the Earth's orbit, the precessional term $e \sin \tilde{\omega}$ ($\tilde{\omega}$ being the longitude of the perihelion measured from the moving vernal equinox) and the obliquity ε (inclination of the equator on the ecliptic):

$$\begin{aligned} e &= e_0 + \sum E_i \cos(\lambda_i t + \phi_i) \\ e \sin \tilde{\omega} &= \sum P_i \sin(\alpha_i t + \beta_i) \\ \varepsilon &= \bar{\varepsilon} + \sum A_i \cos(\gamma_i t + \delta_i) \end{aligned}$$

where $e_0 = 0.028\,706\,9$, $\bar{\varepsilon} = 23^\circ.320\,556$ and time $t = 0$ refers to 1950 AD.

Trigonometric series of this type not only make e , $\tilde{\omega}$ and ε more easily computable, but also provide us directly with a power spectral analysis of their time variation. As in this paper, the main interest lies in the spectrum of the astronomical elements, the period and mean rate associated with the only main largest amplitude terms have been reproduced in Tables 1-3. The computation of e , $e \sin \tilde{\omega}$ and ε will be detailed, and all terms of the trigonometrical expansions will be listed elsewhere.

Table 2 Main terms in the series expansion of the obliquity ε

	Amplitude, A_i	Mean rate, γ_i (" per yr)	Period (yr)	Phase, δ_i (deg)
1	-2,462.2	31.609 974	41,000	251.9
2	-857.3	32.620 504	39,730	280.8
3	-629.3	24.172 203	53,615	128.3
4	-414.3	31.983 787	40,521	292.7
5	-311.8	44.828 336	28,910	15.4
6	308.9	30.973 257	41,843	263.8
7	-162.5	43.668 246	29,678	308.4
8	-116.1	32.246 691	40,190	240.0
9	101.1	30.599 444	42,354	223.0
10	-67.7	42.681 324	30,365	268.8

Mean period over 5 Myr, 41,000 yr.

Taking the precessional component, $e \sin \tilde{\omega}$, the four largest terms have periods of 23,716, 22,428, 18,976 and 19,155 yr. The first two and the last two clearly correspond respectively to the 24,000- and 19,500-yr periods found by Hays *et al.* in deep-sea cores, with the splitting of the theoretical mean period 21,700 yr in two peaks, depending on the resolution of their spectral analysis.

In the obliquity term, not only the dominant component has a period of 41,000 yr but also 5 of the next 10 largest components have periods very close to 41,000 yr. That explains quite well the steadiness of the quasi-periodicity observed in the long-term variations of ε : the mean period over the past 5 Myr is 41,000 yr and over the next 1 Myr it will be 41,040 yr.

For the eccentricity, the situation is still more complicated. As suggested in Berger⁷, the most important term has a periodicity of 412,085 yr—too long to be clear in the analysis of Hays *et al.*—and the convergence of the series is very slow. Because of this, while the weighted mean periodicity for terms 2 to 5 in the expansion is 111,000 yr, the average period from the computed values of e is 95,800 yr, during the past 5 Myr; the prediction for the next 1 Myr being a mean of 91,400 yr. If longer cores can be investigated by

Table 1 Main terms in the series expansion of the precession parameter $e \sin \tilde{\omega}$

	Amplitude, P_i	Mean rate, α_i (" per yr)	Period (yr)	Phase, β_i (deg)
1	0.018 608 0	54.646 478	23,716	32.0
2	0.016 275 2	57.785 364	22,428	197.2
3	-0.013 006 6	68.296 536	18,976	311.7
4	0.009 888 3	67.659 819	19,155	323.6
5	-0.003 367 0	67.286 006	19,261	282.8
6	0.003 330 8	55.638 352	23,293	90.6
7	-0.002 354 0	68.670 349	18,873	352.5
8	0.001 400 2	76.656 031	16,907	131.8
9	0.001 007 0	56.798 442	22,818	157.5

Mean period over the previous 5 Myr: 21,700 yr.

techniques allowing high resolution spectrum, I would expect the 100,000-yr peak to be split into peaks at 95,000 and 123,000 yr, with the main period of 413,000 yr becoming strongly displayed. These 95,000- and 123,000-yr periods are related either to a beat respectively between terms 1 and 3 and between terms 2 and 3 of the $e \sin \omega$ series expansion (Table 1), and to terms numbered 2 and 3 in series expansion of the eccentricity (Table 3).

Table 3 Main terms in the series expansion of the eccentricity e

13	0.001 313 42	12.021 467	107,807	233.0

Mean period over the previous 5 Myr, 95,800 yr.

This prediction is in line with Table 4 of Hays *et al.*⁵ and also with the evidence from their Fig. 9 which suggests a positive correlation between summer temperature and eccentricity during the past 500,000 yr. Indeed, looking for the influence of e alone on the insolation, we can see that it acts only through the $(1-e^2)^{-1/2}$ factor in the total energy received by the Earth¹⁵. As e oscillated between 0.000483 and 0.060791 in the past 5 Myr, it is easily found that the total variation in solar radiation received by the Earth as compared with the present value, is no more than -0.17% or $+0.014\%$. These variations are small, but they are in the right direction according to the results of Hays *et al.*: they are positively correlated with the change in summer temperature and not in the opposite sense, as required by Milankovitch¹⁰, who stated that the influence of e was almost exclusively through the $e \sin \omega$ term. As a consequence, from an astronomical point of view, the 100,000-yr period seems to be closely related either to the nonlinear interaction between the two precession peaks and to the eccentricity period itself if Fig. 9 of ref. 5 can be confirmed.

Some important conclusions may be drawn from the fact that the obliquity peak in geological records is smaller than the $\sim 105,000$ -yr peak or, at least, less dominant than formerly thought¹⁶. Analysing the solar radiation available on the assumption of a perfectly transparent atmosphere¹⁷, it can be deduced that, on the one hand: (1) The insolation received at the equinoxes and the differences between the length of the summer and of the winter astronomical seasons, are functions only of the precessional parameter, $e \sin \omega$. And (2), at the solstices, this parameter has a larger influence than the obliquity. On the other hand: (1) During astronomical seasons, the insolation received at any latitude is a function of the obliquity e . And (2), at high latitudes, the deviations of the insolation from present day values for the caloric seasons are mostly functions of e (ref. 18).

Thus, as the 'eccentricity-precessional beat' period seems to have an important role in past climates as recorded in geological data, the seasonal contrast and the equinoctial or, better, monthly¹⁹ insolation values have to be considered in the modelling of the glacial-interglacial climate fluctuations in addition to or instead of the usual astronomical-caloric seasons frequently used.

Analysing the remaining terms in the trigonometrical expansion of $e \sin \omega$ and e , it seems that the next periods that could be found in geo-ecological records would be, for $e \sin \omega$ around 15,000 and 50,000 yr, for e around 21,000, 31,000 and 54,000 yr and, as far as a combined effect of both precession and obliquity is concerned,

59,000 and 64,000 yr. Discovery of these peaks would remove any remaining doubts about the validity of the astronomical theory of climatic change.

I thank Dr J. Gribbin for reading the manuscript.

LaNi_{5-x}Al_x is a versatile alloy system for metal hydride applications

METAL alloys which reversibly absorb and desorb hydrogen are being used or considered for a variety of energy applications^{1,2}. Alloys of general composition AB₅ are prime candidates because of their good hydrogen absorption/desorption kinetics and large hydrogen storage capacity. The LaNi₅-H₂ system, in particular, has been extensively investigated. In many applications, however, materials are required whose plateau pressures are different from those of LaNi₅H_{6.7}. The desorption pressure of LaNi₅H_{6.7} may be modified by substitutions either of La or Ni with other elements. Previous work³ has shown that 20% substitutions of Ni by a variety of transition metals can lower plateau pressures by a factor of ~ 4 . We report here that Al can substitute for Ni in LaNi₅ with dramatic results in lowering decomposition pressures without impairing the kinetics or the hydrogen carrying capacities. The important new result is that Al substitutions allow a wide range of decomposition pressure to be spanned in continuous fashion. In the range 0-20% Al, the plateau pressures of the LaNi₅-LaNi₄Al hydride system are reduced by a factor of ~ 300 .

Alloys were prepared from metals of 99.9% purity by arc melting on a water-cooled copper hearth in an argon atmosphere. The alloys were homogenised at 800 °C. It was noted that diffraction patterns taken on as cast material were equally as sharp as those taken on homogenised alloys. X-ray diffraction patterns were taken with filtered FeK α radiation. Computer programs were used to verify indexing of the X-ray patterns.

Alloy samples, weighed to ± 0.0001 g, were placed in an all 316 stainless steel reactor fitted with a 1 μ m porous stainless steel filter disk. The reactor was connected to an all 316 stainless steel high pressure manifold with connections to a 0-2,000 lb inch⁻² Heise pressure gauge (accuracy $\pm 0.1\%$), a vacuum pump, and a high pressure hydrogen gas cylinder. Hydrogen was Matheson's pre-purified grade (99.95% min). Hoke valves rated to 3,000 lb inch⁻² were used. The reactor was immersed in a water bath whose temperature up to 80 °C was maintained to ± 0.2 °C by use of a

Thermistemp temperature controller. For higher temperatures a nichrome wound cylindrical furnace was employed. Equilibration was considered to have been achieved when the pressure remained constant for a period of 10–15 min. Equilibration times were generally from 30 min to 2 h. Samples were 'activated' by evacuating the reactor containing the alloy and exposing the sample to high pressure hydrogen (300–800 lb inch⁻²) for 1–2 h. Desorption measurements were performed by removing measured amounts of hydrogen and re-equilibrating the system.

Fig. 1 Plot of $\ln P$ against $1/T$ for $\text{LaNi}_{5-x}\text{Al}_x$ hydrides.

Pressure–composition data have been obtained for alloys of the following composition: $\text{LaNi}_{4.8}\text{Al}_{0.2}$, $\text{LaNi}_{4.6}\text{Al}_{0.4}$, LaNi_4Al , and $\text{LaNi}_{3.5}\text{Al}_{1.5}$. Preliminary data at several temperatures allow us to plot $\ln P$ against $1/T$ for the hydrides of these four compounds. From the slope and intercept of the van't Hoff plots (Fig. 1), ΔH and ΔS values for the reaction

are estimated and given in Table 1.

The increasing stability of the hydrides can also be illustrated by isobaric data as in the last column of Table 1.

X-ray diffraction measurements have been made on a number of $\text{LaNi}_{5-x}\text{Al}_x$ alloys. These results, showing the a_0 and c_0 lattice parameters and the crystal cell volumes as a function of the Al concentration, are illustrated in Fig. 2. The substitution of one Al atom into the 5c and g sites results in a sharp increase in c_0 , and a smaller increase in a_0 . Intensity calculations show that Al tends to enter the 3g sites in preference to the 2c sites. This finding is consistent with an earlier investigation of the $\text{YCo}_5\text{--YNi}_5$ system⁴. Further substitution of Al causes c_0 to level off but a_0 increases at a faster rate. The initial increase in c_0 must result from a lengthening of the bond between layers, while the subsequent levelling off in c_0 results from the beginning of a trend for the large La atom to collapse into the hexagonal ring of Ni(Al) atoms above and below it.

Table 1 Data from $\text{LaNi}_{5-x}\text{Al}_x + n\text{H}_2 = \text{LaNi}_{5-x}\text{Al}_x\text{H}_{2n}$ reaction

Compound	ΔH (kcal mol ⁻¹ H ₂)	ΔS (cal mol ⁻¹ H ₂ °C)	Temperature (°C) for $P = 2.0$ atm
LaNi_5	7.2 ± 0.1	26.1 ± 0.4	~ 25
$\text{LaNi}_{4.8}\text{Al}_{0.2}$	8.3 ± 0.1	27.3 ± 0.4	~ 50
$\text{LaNi}_{4.6}\text{Al}_{0.4}$	9.1 ± 0.2	28.1 ± 0.7	~ 70
LaNi_4Al	12.7 ± 0.3	29.2 ± 0.7	~ 180
$\text{LaNi}_{3.5}\text{Al}_{1.5}$	14.5 ± 0.6	29.6 ± 1.4	~ 240

Fig. 2 Plot of a_0 , c_0 , and V/M against x in $\text{LaNi}_{5-x}\text{Al}_x$ alloys.

Several workers^{5,6,7} have pointed to the importance of crystal structure and geometrical considerations with regards to the stability of metal alloy–hydrogen systems. In Fig. 3, a direct linear correlation between $\ln P_{\text{plateau}}$ and the alloy cell volume is shown for the compounds: LaCo_5 , CeCo_5 , PrCo_5 , NdCo_5 , SmCo_5 , GdCo_5 , YCo_5 , LaNi_5 , PrNi_5 , SmNi_5 , GdNi_5 , LaCo_4Ni , LaCo_3Ni_2 , LaCo_2Ni_3 , NdNi_5 , $\text{LaNi}_{4.8}\text{Al}_{0.2}$, $\text{LaNi}_{4.6}\text{Al}_{0.4}$, and LaNi_4Al . The observed trend of lower plateau pressures with increasing Al content is in agreement with the cell volume correlation observed for other AB_5 compounds.

Fig. 3 Plot of $\ln P$ against alloy cell volume for AB_5 type hydrides, with ref. nos. See ref. 8 for LaCo_5 , CeCo_5 , PrCo_5 , NdCo_5 , SmCo_5 , GdCo_5 ; ref. 9 for YCo_5 ; ref. 10 for LaNi_5 ; ref. 11 for PrNi_5 , SmNi_5 , GdNi_5 ; ref. 12 for LaCo_4Ni , LaCo_3Ni_2 ; LaCo_2Ni_3 ; ref. 13 NdNi_5 ; the present work (ref. 14 on Fig.) for $\text{LaNi}_{4.8}\text{Al}_{0.2}$, $\text{LaNi}_{4.6}\text{Al}_{0.4}$, LaNi_4Al .

A new ternary alloy system has been developed involving Al substitution of Ni in AB_3 compounds which permits control of hydrogen decomposition pressures over wide pressure and temperature ranges, while preserving the excellent hydrogen absorption-desorption kinetics and large hydrogen carrying capacity of $LaNi_5$.

This work was performed under the auspices of the Division of Physical Research of the U.S. Energy Research and Development Administration.

Ni-Sn interaction in temper embrittled steel detected by Mössbauer spectroscopy

PREREQUISITES for reversible temper embrittlement of steel¹ are the presence of a trace impurity² (Sb, Sn, As or P) and a major alloying element^{3,4} (Ni, Cr or Mn). Auger electron spectroscopy (AES) demonstrated that in the embrittled state these elements are segregated to within the first few monolayers of the high angle boundaries^{5,6}. The segregation is reversible and can be removed by heating at temperatures above the embrittlement range, whilst still within the α field (that is $> 600^\circ\text{C}$). It has been postulated⁷ that the segregation behaviour can be explained using equilibrium thermodynamics. It is proposed that the trace impurities interact more strongly with the major alloying elements than the Fe matrix and hence the chemical potential of the system is reduced by segregation to the high angle boundaries with the formation of bi-dimensional complexes (such as Ni_3Sn_2 , Mn_3P and Cr_3P). No experimental evidence is available for the existence of such complexes. AES gives no information regarding the chemical bonding of the segregants but it has been shown⁸, using X-ray photoelectron spectroscopy (XPS), that the segregated Mn on embrittled fracture surfaces of a 2% Mn steel is in a different chemical state to that on unembrittled surfaces. We report here preliminary results from a specially prepared 3% Ni steel, doped with ^{119}Sn , which were obtained using Mössbauer spectroscopy to monitor changes in the nearest-neighbour atoms of the Sn atoms as a function of heat treatment in the temper embrittlement temperature range.

Argon arc melting was used to prepare the high purity alloy of composition (wt%) Ni (3.4); ^{119}Sn (0.19); C (0.10); Fe (balance). The cast alloy was rolled to a thickness of 100 μm , an optimum thickness for the Mössbauer measurements, and austenitised for 1 h at $1,120^\circ\text{C}$ followed by a water quench. Heat treatments were chosen to produce

Table 1 Heat treatment schedule

Condition	1120 °C	650 °C	500 °C	650 °C
As quenched	1 h, water quench			
Unembrittled	1 h, water quench	1 h		
Embrittled	1 h, water quench	1 h	1,000 h	
De-embrittled	1 h, water quench	1 h	1,000 h	1 h

conditions representative of: the martensitic water quenched material, the unembrittled state, the embrittled state and the de-embrittled state, as detailed in Table 1. Mössbauer spectra were recorded in transmission at 77 K using a CaSnO_3 source and a constant acceleration spectrometer.

The Mössbauer spectra in Fig. 1 were found to consist mainly four components tentatively identified with Sn atoms having 0, 1, 2, or 3 Ni nearest neighbours. As the field in pure Fe is -8.5T and in Ni is $+2\text{T}$, the magnitude of the field is expected to decrease with increasing number of Ni nearest neighbours. At least-squares computer programme adjusted the intensities and magnitude of the fields of the four components to fit the spectra, and the percentages of the components are shown in Table 2. The errors are estimated to be $\pm 5\%$. With increasing number of Ni neighbours a progressive positive isomer shift was observed, indicating an increasing s electron density at the Sn nuclei. The total shift of 3 Ni neighbours was 0.22 mm s^{-1} .

For the as quenched material, the analysis showed a slightly greater percentage of Sn atoms having Ni nearest

Fig. 1 Mössbauer spectra obtained for *a*, the as quenched martensitic material; *b*, the unembrittled state and *c*, the embrittled state. On de-embrittling, the spectra reverted to that of the unembrittled state.

Table 2 Percentage of Sn atoms

No. of Ni nearest neighbours	0	1	2	3
Calculated value for random distribution (bcc)	76	21	3	0
As quenched	71	24	5	0
Unembrittled	62	32	10	6
Embripped	33	23	22	22
De-embripped	53	26	13	8
Field (T)	-8.5	-4.9	-2.1	-0.7

neighbours than that predicted from a random solid solution, indicating the presence of a Ni-Sn interaction within the γ field. Tempering at 650 °C (the unembrittled state) produced a further increase in the percentage of Sn atoms having Ni neighbours. On tempering at 500 °C, a dramatic change in the spectrum was noted and the analysis showed this is due to an increased number of Sn atoms having two or three Ni nearest neighbours. On re-heating at 650 °C (the de-embrittled state) these components were removed from the spectrum which reverted to that of the unembrittled state. The possibility of compound formation during tempering at 500 °C was examined by a comparison with the Mössbauer spectra produced by Ni_3Sn_2 or Ni_3Sn_4 . Within the accuracy of the experiments, the distinction between compound formation and Sn having three Ni nearest neighbours could not be resolved but is the subject of further investigation.

Examination of thin foils of the specimens in the embrittled condition using transmission electron microscopy failed to identify any compound formation either within the grains or at the grain boundaries. However, since AES⁹ has demonstrated that Ni and Sn are segregated at the boundaries of temper embrittled steels, it is reasonable to conclude that the modification of the spectra on ageing at 500 °C is due primarily to a grain boundary centred phenomenon associated with either the formation of a bi-dimensional phase of the type Ni_3Sn_2 (or Ni_3Sn_4) or due to an increased Ni-Sn coupling. The removal of this 'phase' on re-heating at 650 °C, above the embrittling temperature range, indicates that it has a critical role in the mechanism of temper embrittlement.

This work has demonstrated the existence of a reversible Ni-Sn interaction when subjected to a classical embrittling-de-embrittling treatment. This interaction is considered to be primarily centred at the grain boundaries and is related to either the increased number of Ni nearest neighbours of the Sn atoms or due to a bi-dimensional compound formation of Ni_3Sn_2 or Ni_3Sn_4 . Our work has shown that Mössbauer spectroscopy is a powerful tool for monitoring the environment of the Sn impurity atoms in temper embrittled steels as a function of heat treatment, and a similar evaluation may also be possible for Sb.

Water content of Russian tektites

THE first occurrence of tektites in Russia was reported recently by Florensky¹⁻³, who named them irgizites, and concluded that they were produced by fusion of terrestrial rocks at the Zhamanshin impact structure where they are found. The Zhamanshin impact structure is approximately 10 km in diameter and is 200 km north of the Aral Sea (~49°N, ~59°E). The irgizites have the splash forms that are commonly found among other tektites and impactites, for example, indochinites and Wabar glass. Although Florensky clearly describes the field occurrence, shapes, general petrography, major element chemistry and origin of the irgizites, the reported bulk chemical analysis of the major elements includes neither ferrous/ferric iron nor water³. Thus, data for two of the most widely accepted chemical criteria for the identification of tektites have not previously been available for irgizites. This note reports investigations into their water content.

Seven irgizites were obtained, one of which was available for destructive analysis. A thin plate was cut from this specimen, polished, and the water content of the glass was determined using the technique of Gilchrist *et al.*⁴ from the infrared absorption spectrum (Fig. 1). A moldavite and a terrestrial obsidian sample were run under the same conditions for comparison. The actual water determination for the irgizite was made on a slice 2.1 mm thick, and the value obtained was 0.051 weight per cent water. This figure is greater than the water content of the presently recognised tektites, which average approximately 0.01 wt % (ref. 4).

Fig. 1 Infrared absorption spectra of a moldavite, irgizite and an obsidian. Spectra were obtained from doubly polished sections 0.290 mm thick (moldavite), 0.275 mm (irgizite) and 0.180 mm (obsidian). The respective water contents are: moldavite, 0.0092; irgizite, 0.051; obsidian, 0.156 wt %. The water content of the irgizite is greater than that of true tektites.

In thin section, the body glass of the irgizite is a light olive brown colour, similar to many bediasites, and probably indicates a high ferrous/ferric iron ratio, but sufficient material was not available for a wet chemical determination. Partial electron microprobe analyses of the irgizite glass show a range of composition that is commonly found within a single tektite, and confirm the presence of lechatelierite inclusions³. The body glass of the irgizite is very clean with schlieren and slightly different colour and refractive indices; it also contains a number of spherical to elliptical bubbles, congruent in number and size with the bubbles in many tektites. There are no microlites nor any other traces of devitrification or

hydration. A few tiny and rare mineral grain inclusions are present, but they are too small to identify.

The piece of irgizite glass we examined seems to be a typical tektite glass in all respects except for the greater water content and possibly the, as yet undetermined, ferrous/ferric iron ratio. Whether or not the irgizites should be classified as tektites is a moot question. Perhaps they should be termed wet tektites, but regardless of their name, they are extremely similar to, and have originated by, the same basic process as true tektites.

Although the fundamental question of the place and mode of origin of tektites has been resolved for some years⁵⁻⁹, the irgizites are an important link in the chemistry and petrography of terrestrial impactites from craters of small to intermediate size.

The authors are indebted to Walter Zeitschel of Hanau for providing the specimens of irgizites used in this work.

Source models to account for Lake Mungo palaeomagnetic excursion and their implications

INDICATIONS of large and rapid excursions in the direction of the ancient geomagnetic field continue to create considerable excitement and debate in palaeomagnetic circles. Barbetti and McElhinny¹ have published detailed evidence of a remarkable excursion at Lake Mungo, Australia dated at about 30,000 yr ago, on which they had briefly reported previously². I consider here various simple sources, all in the Earth's outer core, that could account for that excursion—an eccentric radial dipole or current loop, an eccentric horizontal dipole, and a pair of eccentric radial current loops of opposite sign—and discuss the merits of each in light of the modern geomagnetic field and with regard to the magnitude and spatial extent of the anomalous field produced.

Because most of the excursions proposed so far have been found in sediments and have not been convincingly documented over a sizeable portion of the globe, several workers have suggested that

some or most of them may reflect sedimentological rather than geomagnetic phenomena³⁻⁵. The record of the Lake Mungo excursion, however, is contained in sedimentary material that was baked in prehistoric aboriginal fireplaces. Thus, sedimentological phenomena cannot be invoked to explain the anomalous directions because the natural remanent magnetisation is not detrital or diagenetic in origin but rather is thermoremanent. This type of magnetisation is not only the most reliable recorder of ancient field direction but is also the best suited for making estimates of ancient field intensity.

The Lake Mungo excursion is especially intriguing because of the very high field intensity that Barbetti and McElhinny¹ have found accompanying the large swing in field direction. The intensity estimates are as high as 1.83 Oe, about twice as strong as anywhere on the surface of the Earth today and three times what would be produced at that latitude by the maximum geomagnetic dipole moment previously reported for the past 8,500 yr (ref. 6). While the field was abnormally intense its direction was shallowly inclined first roughly west and then roughly east, very far from the normal field direction of an approximately axial and centred dipole.

The explanation of this phenomenon with the least astonishing consequences is that some of the palaeointensity measurements are erroneously high. It is well known that ancient field intensities are far more difficult to determine than directions because of the many possibilities for systematic error⁷. Nonetheless, we cannot easily dismiss these extraordinarily high palaeointensities. Barbetti and McElhinny¹ carefully discuss the probable effects of a great number of possible systematic errors and conclude that their estimates of palaeointensity should be regarded as minimum values. Moreover, the high values were found at three sites in samples of two different sorts of baked sediment, whereas at several other sites these same materials yield both normal and unusually low estimates of palaeointensity. Thus, it is most useful at this point to accept the measurements of direction and intensity as at least approximately correct and to examine other explanations and their consequences.

The failure so far to find convincing evidence for any single excursion at widely separated points on the globe has led to the suggestion that excursions are manifestations of the non-dipole field^{8,9}. Likewise, Barbetti and McElhinny¹ propose that the most likely cause of the Lake Mungo excursion is the occurrence of a very large intensity non-dipole feature which may be modelled approximately by an eccentric, radially-oriented dipole in the core near the core-mantle boundary beneath Lake Mungo. They point out that such a radial dipole at 0.5 R (offset from the centre of the Earth by 0.5 of the Earth's radius) would need a moment of only one-eighth that of the main geocentric dipole to produce at the point on the surface nearest to it a field greater than or equal to that of the main dipole, whereas on the far side of the Earth it would produce a field only 1/27 as large.

Even higher field intensities, however, are required elsewhere on the surface of the Earth when one attempts to apply the radial dipole model in a quantitative manner to the Lake Mungo excursion (Fig. 1a). To do this, I have assumed that the dipole field at the time was axial and had an intensity 0.3 Oe at the site. This is the most reasonable assumption in accordance with the data¹, but

Table 1 Solutions for radial dipoles corresponding to Lake Mungo excursion

Non-dipole field				Nearer solution				Farther solution			
Site	F_N	F_E	F_D	λ	ϕ	M/M_0	θ	λ	ϕ	M/M_0	θ
F7*	-0.68	-0.76	0.27	-52	81	-1.4	48	13	186	2.3	62
F12	-0.44	-1.81	0.14	-29	80	-3.1	53	-8	199	3.6	57
F8	-0.06	0.57	0.14	-26	198	-0.8	48	-11	80	1.3	62
F9*	-0.37	1.18	0.25	-34	203	-1.8	49	-3	87	2.7	60

Sites are those of Barbetti and McElhinny². F_N , F_E , F_D are north, east, downward non-dipole field components in Oe (10^{-4} T). λ , ϕ , and M/M_0 are north latitude, east longitude, moment divided by present geocentric dipole moment of radial dipole. θ is great-circle angle in degrees between radial dipole and site.

*Palaeointensity is average of values derived from ovenstone and baked sediment².

other plausible choices such as the present inclined dipole field of approximately 0.6 Oe at Lake Mungo do not seriously change the results. The differences between the palaeomagnetically determined total field vectors and the presumed dipole field vector are the ancient non-dipole field vectors (Table 1), for which one seeks to find the appropriate radial dipole sources.

Two possible solutions always exist for a radial dipole at any particular depth that can produce a given field at a site on the surface. These can be found using standard formulas¹⁰ and an iterative technique. The dipole nearer to the site naturally has a smaller moment than the one further away that produces the same field. Thus, it is the nearer dipole that is the more likely to correspond to the real physical situation if the non-dipole field at the site is in fact produced by only one such source. The depth of the radial dipole that is best used depends on the width of the anomaly to be modelled at the surface. Assuming non-dipole features in the past to have been similar to those of today, offsets of 0.35–0.45 R are most appropriate. These correspond to half-widths of 44–56° great circle arc for the vertical component of the anomaly.

The solutions for the positions and strengths of radial dipoles with offset 0.40 R that would produce the non-dipole field vectors for the Lake Mungo excursion are given in Table 1. The nearer solutions are inward-pointing dipoles at southerly latitudes of 26° or higher and at longitudes around 80°E or 200°E for the sites with westerly or easterly palaeomagnetic declinations, respectively. The farther solutions are only about 11° more distant on the average than the nearer solutions, and are outward-pointing dipoles lying within 13° of the equator at longitudes around 190°E or 85°E. The solutions are listed in order of presumed decreasing age and span a period of 2,000–3,000 yr (ref. 2).

The moments of even the nearer radial dipoles are enormous, ranging from 0.8–3.1 times the present geocentric dipole moment, and the alternate farther dipoles are up to 60% stronger than the nearer ones. These hypothetical dipoles would cause extremely large intensities at the points on the surface nearest to them of 2.3–8.8 Oe. Even at the antipodal points the intensities are about 0.2–0.7 Oe, certainly not negligible compared with usual field intensities.

Shifting the radial dipole toward or away from the centre of the Earth does little to diminish the excessively high field intensities. A radial dipole just below the core–mantle boundary (0.54 R) or just above the inner core (0.20 R) that produces the largest non-dipole field vector inferred for Lake Mungo (that at site F12, Table 1) would produce field intensities over the whole Earth ranging from 10.6–0.3 Oe or 6.1–1.8 Oe, respectively. Likewise, replacing the simple point dipole by a distributed source such as a circular loop

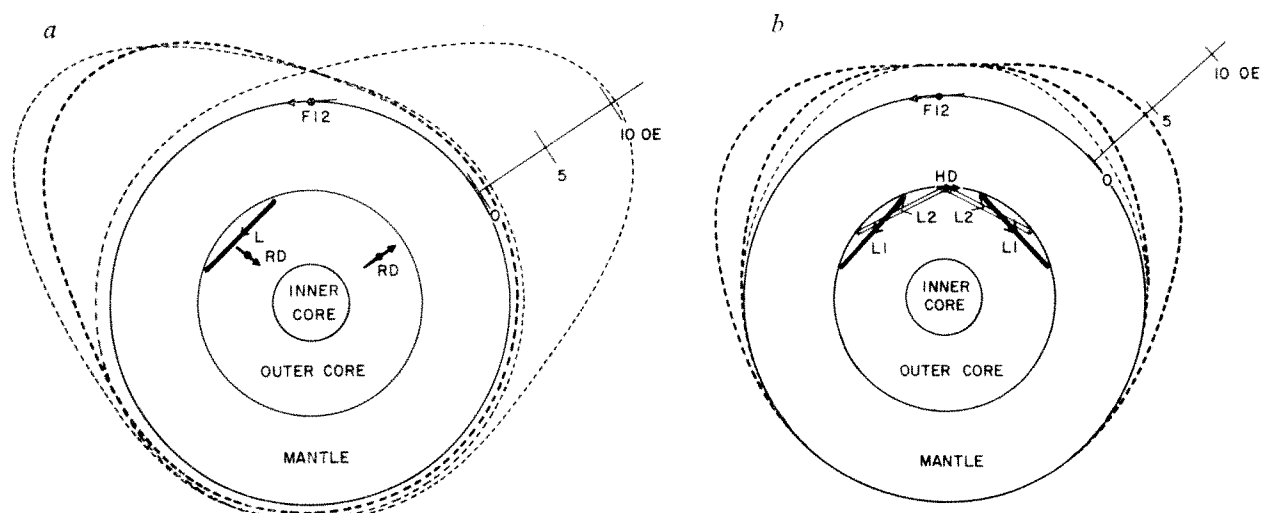

of current at the core–mantle boundary is only a minor improvement. Such a current loop with radius 44% of the radius of the core, which would cause an anomaly at the surface of about the same width as a radial dipole at 0.40 R, would bring about intensities over the world ranging from 7.2–0.4 Oe, while producing the largest non-dipole field vector inferred for Lake Mungo. Variations of the total field intensity for various of these models are illustrated in Fig. 1a.

The only way for such a large, almost horizontal non-dipole field as apparently occurred at Lake Mungo to exist without much larger fields existing simultaneously elsewhere on the Earth is to relax the assumption that the cause was a simple, radial source. When two adjacent radial sources have opposite signs, their horizontal components add between them and the area dominated by their combined fields is much less than for a single source. For example, consider the current loop described above and a slightly stronger current loop of opposite sign, 96° away from the former on the other side of Lake Mungo, that would also produce the same field at site F12. If reduced to half their strengths, the two loops together would likewise cause the required non-dipole field at site F12, but over the rest of the Earth they would produce fields that varied from only 4.5 to almost 0 Oe (Fig. 1b). If the current loops were allowed to overlap slightly, the most efficient configuration would be two current loops of equal strength and opposite sign spaced 54° apart. Such a pair would cause fields that varied from only 2.3 Oe to exactly 0 Oe over the globe (Fig. 1b), while producing the required 1.87 Oe at site F12. The spacing of 54° lies at the short end of the observed range of about 50–100° for the spacing of adjacent features of opposite sign of the modern non-dipole field¹¹.

The other assumption that might be relaxed is that the source is radial. A horizontal dipole at the core–mantle boundary would only require a strength of about 20% or less of the present main geocentric moment to account for the non-dipole fields inferred at Lake Mungo. This dipole would cause field intensities over the globe varying from about 2.0 Oe to less than 0.05 Oe (Fig. 1b). Combinations of two horizontal dipoles could reduce still further the maximum field intensities and the area of the globe significantly affected.

What, then, is the most likely source for the very high intensity Lake Mungo excursion? A horizontal eccentric source or current loop is the most efficient in terms of causing the least disturbance of the field elsewhere around the world, but there is little basis for expecting one to exist since the modern non-dipole field is dominated by a few large features that are most simply modelled by radial sources^{10,11}. Single radial sources, however, would produce

Fig. 1 Magnetic field intensity at Earth's surface due to various sources in outer core. Dashed lines indicate total field, zero if coincident with surface of Earth. Each source produces the palaeomagnetic non-dipole field at Lake Mungo site F12 (Table 1). *a*, Single radial sources: radial dipole at 0.40 R (RD), light dashed lines; current loop (L), heavy dashed line. *b*, Paired radial sources or horizontal source: current loops of opposite sign (L1 or L2), heavy dashed lines; horizontal dipole (HD), light dashed line.

extremely high fields over very large areas and significantly high anomalous fields over the entire globe. Thus, they are improbable unless simultaneous worldwide effects are discovered. The most appealing explanation seems to be a combination of two radial eccentric sources of opposite sign. In their most efficient configuration such a pair would cause a maximum field of about 2.3 Oe, while producing the required non-dipole field at Lake Mungo (site F12), and significant effects would occur as far away as south-eastern Asia and India, southern Africa, and much of Antarctica and the South Pacific Basin.

To produce all four non-dipole fields listed in Table 1, such a pair of sources would have to change signs and move about 15° N and S, in a similar fashion to the oscillating radial dipoles of fixed average position recently postulated by Creer¹² in explanation of geomagnetic secular variation. Although it could well be coincidental, it is interesting that two of the oscillating dipoles proposed by Creer lie within 10° and 25° of the average positions of the optimally-spaced pairs of current loops calculated to produce the field directions of the Lake Mungo excursion.

Obviously, there is a critical need for additional records of the Lake Mungo excursion in other places around the world. Only these will provide firm answers to fundamental questions such as whether the excursion is an expression of the dipole or non-dipole field and whether the very high field intensities inferred from the experimental data are in fact real. If the non-dipole field is responsible, such records are also necessary to determine the shape, number and configuration of the sources. At present, one can only conclude that if the very high field intensities are approximately correct and if the excursion was caused by non-dipole features similar in configuration to the modern ones, then unusually strong non-dipole fields must have occurred simultaneously over a significant portion of the rest of the world.

I thank Dr M. F. Barbetti, Dr M. W. McElhinny, Dr C. S. Grommé and Dr A. Cox for discussions, and the Australian National University for partial support provided by a visiting research fellowship.

Trace elements in zooplankton particulate products

It has become increasingly evident that biogenous processes in oceanic surface layers play an important role in removing trace elements from sea water and transporting them to the sediments^{1,2}. Plankton are strongly implicated in these processes and investigations of the chemistry of these organisms have demonstrated their ability to accumulate trace elements to relatively high levels^{3,4}. Zooplankton metabolic activity can be expected to enhance the biogeochemical cycling of trace elements through the release of particulate matter⁵ such as faecal pellets, moulted exoskeletons and eggs. Furthermore, theoretical models^{5,6} on the vertical flux of particulates have emphasised the sinking of large particles, similar to those produced by zooplankton, as a mechanism for rapid transport of particulate matter

and associated trace elements out of the mixed layer. Nevertheless, little, if any, data exist on the trace element composition of these biogenic particles, and Boyle *et al.*⁷, interpreting their Pacific Ocean Cd profiles in terms of probable Cd regeneration from sinking biogenic debris, have stressed the need for information on the trace element composition of planktonic particulate matter. This note reports the concentrations of 18 trace elements in freshly released faecal pellets, moults and eggs from a representative planktonic crustacean. The high levels of many trace elements found in these biogenic products, relative to concentrations in the plankton which produce them, clearly indicate the importance of these particulates in oceanic trace element biogeochemical cycles.

Many euphausiids (*Meganyctiphanes norvegica*) were collected during one night in the surface waters off Monaco by making several, short oblique tows with a midwater trawl. Approximately 1,000 individuals were placed in a faecal pellet collection system⁸ and several hundred milligrams (wet) of pure faecal pellets were retrieved after 15 h. The remaining euphausiids were split into two groups; one was maintained in the laboratory⁹ until a sufficient number of moults had been collected and the other was killed for whole body analysis. Eggs released by females were concentrated from the water on fine mesh nylon netting. Microplankton, on which *M. norvegica* were feeding, were collected at the same time for purposes of comparing their trace element contents with levels in the euphausiid faecal pellets. All samples were briefly rinsed with doubly distilled water to remove adhering sea salts and oven-dried at 60 °C. Separate aliquots of material intended for Hg analysis were freeze-dried in order to avoid Hg loss through volatilisation. Care was exercised to avoid metal contamination at all stages of collection and sample preparation. Microplankton samples were carefully screened for possible metal-particle contamination using the Martin and Knauer⁴ method. Samples along with appropriate blanks and standards were analysed by flameless or flame atomic absorption spectrophotometry¹⁰ and instrumental neutron activation¹¹.

Trace element concentrations in euphausiids, their particulate products and the food they eat are given in Table 1. Since all samples were derived from the same water mass, realistic comparisons can be made between trace element levels in the particulates and those in the organisms which produced them. For most elements, faecal pellets contained the highest trace element levels with lesser amounts in moults and eggs. Trace element concentrations in faecal pellets were significantly higher than levels in whole euphausiids (as much as 1,000 times) except for Sr and possibly Hg and Se. The natural diet of *M. norvegica*, an omnivore, is extremely varied¹² but consists primarily of phytoplankton, small zooplankton and detritus. Although it is difficult to define precisely the exact composition of their diet at any given moment, examination of euphausiid stomach contents and faecal pellets indicated that the samples were feeding on many of the species noted in the microplankton. Comparison of the trace element content in microplankton and euphausiid faecal pellets in Table 1 shows that, except in the case of Sr, euphausiids readily concentrate ingested trace elements in their faeces. Faecal pellet-microplankton concentration ratios ranged as high as 670 with the greatest degree of concentration noted for trace elements not biologically essential such as Ce, Sb, Cs, Eu and Sc. The high concentration ratio for Fe, a biologically essential element, is possibly a result of ingesting a particulate form of this metal which may not be easily assimilated. Boothe and Knauer¹³ have also reported a relatively high concentration of Fe in crab faeces relative to that in their food.

With the exception of Cu, Cs, Hg and Se, trace element concentrations in moults were also significantly higher than

Table 1 Trace element concentration ($\mu\text{g g}^{-1}$ dry) in a planktonic euphausiid, its particulate products and the microplankton it ingests

corresponding levels in whole individuals (Table 1). Bertine and Goldberg¹⁴ analysed several trace elements in shrimp and found that Zn and Ag were higher in dissected exoskeleton than in internal tissues. When small pelagic crustaceans moult, only the thin outer layer of the exoskeleton is shed. If surface adsorption predominates in the accumulation of many of the trace elements on to chitinous moults, as is the case for several radionuclides¹⁵, it is conceivable that moults will contain higher concentrations of these elements than the entire exoskeleton.

M. norvegica moults average 7.7% of the organism's dry weight; from this, rough estimates of the fraction of the animal's trace element content contained in the moult can

than moults in effecting element transport, since egg deposition is seasonal. Zooplankton faecal pellets, which are produced at a higher rate¹⁹ and decompose more slowly²⁰ than moults, clearly have the greatest potential for transporting trace elements to depth. Recent finding of large numbers of intact faecal pellets in deep waters^{21, 22} supports this contention. Trace element flux rates resulting from the release of moults and faeces by euphausiids can be calculated and are given in Table 3. From a comparison of the rates it is clear that, with the exception of Sr, faecal pellet flux is a major contributor to the biogenic vertical transport of the elements investigated. Thus, vertical transport through faecal pellets may be an important factor

Table 2 Fraction of euphausiid trace element body burden contained in the moult

*Calculations based on p.p.m. dry weight values listed in Table 1.

be calculated (Table 2). Clearly, for many trace elements, a large fraction of the euphausiid's total body burden is associated with its outer surface. The reason for the anomalously high Pb percentage is not readily explainable and measurements made on another set of samples led to a similarly high percentage. The possibility of contamination can not be entirely ruled out; however, Pb is known to be highly concentrated on the epidermis of marine fish¹⁶, and

influencing the oceanic residence times of these elements. The degree to which faecal pellets and other biogenic debris transport their trace element load to depth will be a function of trace element regeneration time for these sinking materials. Considering the high trace element content of freshly released zooplankton particulate matter, some attempt to understand *in situ* trace element regeneration kinetics in these products is needed.

Table 3 Trace element flux rate contribution (μg per kg euphausiid per d) by euphausiids*

	Ag	Cd	Co	Cr	Cu	Fe	Mn	Ni	Pb	Zn	Ce	Cs	Eu	Hg	Sb	Sc	Se	Sr
Faecal pellets	80	360	130	1,400	8,600	910,000	9,200	760	1,300	36,000	7,600	230	25	13	2,700	110	250	3,000
Moult	26	19	7	48	320	2,100	110	60	200	1,300	11	0.2	0.07	1.5	7	0.3	17	3,200

*Based on typical *M. norvegica* faecal pellet and moult production rates¹⁹ of 0.038 and 0.009 g dry matter per g dry euphausiid per day, respectively. Flux due to egg deposition is not considered since egg production takes place for only a brief period during the year¹⁹.

it may be that the cast moult adsorbed additional Pb on its inner surface before it was removed from the water. Nevertheless, the implication is that most or all of the Pb associated with euphausiids is located on the surface of the exoskeleton.

The relatively high concentrations of so many trace elements in zooplankton particulates hold important implications for marine biogeochemical cycles. Pelagic crustaceans moult as often as every few days^{9,17,18}, in some cases throughout their entire lifespan. Consequently, sinking moults may either release trace elements to the deeper waters or sediments during decomposition or, if eaten, provide a rich source of trace elements to organisms that consume them. Released eggs, often also displaying a relatively high trace element content, will be much less important

Weis-Fogh clap and fling mechanism in *Locusta*

WEIS-FOGH discovered a mechanism of lift generation¹ when he observed, from slow motion films, that the tiny parasitic wasp *Encarsia* clapped its wings together at the top of the stroke during hovering flight; the clap was followed by a 'flinging open' of the wings, as they rotated about a common axis where the hindwing trailing edges were in contact. He calculated that the insect generated greater lift than could be explained by steady-state aerodynamics. The importance of the clap and fling in generating this extra lift is now well established²⁻⁴. We report here that slow motion film of natural flight has revealed this mechanism in locusts and that it occurs during forward flight to produce extra lift.

Swarms of *Locusta migratoria* were filmed with a high-speed camera in Australia and New Guinea. Film taken pointing directly towards an approaching and climbing swarm revealed that the hindwings of the locusts met at the top of the stroke in a similar fashion to that observed by Weis-Fogh in *Encarsia*. During the clap the tips of the hindwings meet, leaving a characteristic gap lower down towards

the wing bases. At the beginning of the downstroke, the leading edges of the hindwings part, but the more posterior vannal portions remain touching; as the hindwings move further down, the two wings eventually become completely separated from one another and they then progress as in a normal stroke. Significantly this clap and fling stroke is seen only in climbing locusts, which need greater lift than locusts in horizontal flight. Aspects of the stroke can be seen in Fig. 1.

The hindwing movement on the upstroke, before the clap, is noticeably faster than in a non-clapping stroke, and Fig. 2a shows this remarkably rapid upstroke which can be twice as fast as its forewing counterpart; hindwing tip speeds up to 10 m s^{-1} have been calculated from the film. Differences in phase between the fore and hindwings during the clap stroke seem to be essentially similar to those in the normal non-clap stroke (see Fig. 2b), and thus the hindwings move through a greater amplitude before the clap simply by moving faster than usual, reaching the top of their stroke with about the same phase lead over the forewings as in a non-clap stroke. Only the amplitude difference between fore- and hindwings changes markedly, and this results in a characteristic configuration with the hindwings pointing vertically and the forewings pointing horizontally (see Fig. 1).

On some of the high-speed film an occasional butterfly (unknown species) was seen flying across the field of view. Like the locusts, they also performed a wing clap at the top of the stroke⁴; in some cases the clap together was not immediately followed by separation as in the locusts, and instead the wings were held closed for a fraction of a second. The clap was observed both in approximately horizontal and vertical flight.

The clapping of the locust hindwings might be expected to make a noise, as is the case with pigeons taking off⁵. There are several reports of locust flight noises, especially during take-off⁶. Experiments performed in the field^{7,8} showed that the hindwings were responsible, and variously attributed the noise to the interaction of hindwings with back legs⁹, or to stretching of the vannal area of each

Fig. 1 Sequence of hindwing clap and fling in *Locusta*. Wings meet directly above the body and then at the start of the downstroke, the leading edges open, leaving more posterior portions of the wing still in contact. (Each frame is taken from a different locust.)

Fig. 2 *a*, Wingbeat cycles of right fore and hindwings of a locust performing clap. *b*, Wingbeat cycles of a different locust during non-clap strokes. 180° refers to wings in vertical clap position, and thus 90° is wings in horizontal position.

hindwing¹⁰. We suggest, however, that the noise is caused by the hindwings clapping together, this being likely to make a louder noise than the more proximal parts of the hindwings striking the legs. In the case of the locust *Dissosteira carolina*¹¹, which can apparently produce noise whilst hovering over a nearly fixed point, it performs a type of aerial dance and noise display thought to be of a sexual nature; we therefore suggest that the clap and fling mechanism may have a secondary sexual function in this case.

The significant aspect of these findings, both in locust and butterfly, is that the clap and fling mechanism seems to be used in forward flight as well as hovering, and thus must now be recognised as an aspect of primary importance in insect flight.

We thank Professor Sir James Lighthill for encouragement and advice, and CSIRO, Canberra for support in the field.

Post-metamorphic eye migration in *Rana* and *Xenopus*

CONTRADICTORY results have been obtained with *Xenopus laevis* and *Rana pipiens* in experiments directed at evaluating the possible role of visual experience in assuring proper binocular relations in the optic tectum. Gaze, Keating, and colleagues, working with *Xenopus*, reported that, in certain circumstances, experimental alteration of the contralateral visuotectal projection by eye rotation results in a modification of the ipsilateral projection so as to re-establish appropriate binocular relations^{1,2}. Jacobson and co-workers, however, working with *Rana*, reported no change in the ipsilateral projection after experimental rotation of the eye³⁻⁶. Based on the hypothesis that the ability to respond to experimental perturbation of interocular relationships would correlate with the amount of variation in interocular relationships occurring normally, we predicted that *Rana* might exhibit substantially less post-metamorphic eye migration than *Xenopus*. We report here results which confirm this prediction.

In both *Xenopus*⁷ and *Rana*³, the ipsilateral visuotectal projection develops during metamorphosis, when the eyes migrate from lateral positions, with little or no overlap of their visual fields, to positions with significant binocular overlap. Because we were concerned with possible changes in interocular relationships occurring after the ipsilateral projection has developed, we concentrated our attention on relative eye position from the completion of metamorphosis onwards. Keating⁸ drew attention to the fact that eye migration continues for some period post-metamorphically in *Xenopus*. We here provide quantitative confirmation of a continual change in relative eye position in post-metamorphic *Xenopus*. In contrast, we have found that relative eye position is stable post-metamorphically in *Rana*. The photographs in Fig. 1 illustrate these basic conclusions. Figure 1*a* shows the relative eye position in a *Xenopus* froglet in the final stage of metamorphosis, as well as in an older juvenile and in an adult. The eyes continue to migrate dorsally, towards each other, after the end of metamorphosis. Similar photographs, however, for the *Rana* froglet and adult (Fig. 1*b*) show strikingly similar relative eye positions.

To quantitate these observations we devised a modification of the techniques used by Fite⁹ to determine the extent of visual fields with relation to body axes in frogs and toads. *R. pipiens* and *X. laevis* were reared in the laboratory from fertilised eggs and adults were obtained commercially. At known metamorphic stages or post-metamorphic ages individuals were either anaesthetised or paralysed and mounted at the centre of and facing towards an Aimark projection perimeter. An ophthalmoscope held in a moveable clamp was used to illuminate the eye and to visualise light reflected from within it. Once this was done the ophthalmoscope was moved peripherally in the visual field until the reflected light just disappeared. The ophthalmoscope was then kept in this position while a mirror was used to intercept the light beam and reflect it back through the ophthalmoscope onto the perimeter where its position was noted as an angle with respect to body axes. Repetitions of this procedure for both eyes with different directions of movement of the ophthalmoscope outlined the extent of the anterior half of the two visual fields. The whole process was then repeated with the animal facing away from the perimeter, giving the posterior half of the visual fields.

Results are shown in Fig. 2. In all cases, data from four or more animals have been included to indicate the range of variations which along any meridian or

parallel rarely exceeds 10° . A fair amount of this variation is attributable to uncertainties in the procedure itself, since repeated determinations in a single animal give comparable variations. It is clear from Fig. 2a and b that there is little or no difference in relative eye position between an immediately post-metamorphic and an adult *Rana*. For *Xenopus*, however, there is a significant amount of dorsal movement of the eyes subsequent to metamorphosis (Fig. 2c, d). The migration involves a shift of the visual axis of about 30° , is half completed at 7 wk, and still in progress at six months (Fig. 2e). There is apparently no substantial change in monocular visual field size or shape over this period.

The significance of the continuing eye migration in *Xenopus*, as pointed out by Keating⁸, is that, unless there is complicated reorganisation of the retinae, the region of one retina which is directed at the same part of visual space as a given region on the other is constantly changing. In these circumstances constant readjustment of the binocular interactions by the use of visual experience may be an essential developmental mechanism for maintaining the appropriate interactions between the two eyes. The results of experimental rotation of one eye may be interpreted as indicating the presence of such a mechanism operating during normal development. In *Rana*, however, as we have shown, the developmental problem of constant readjustment of binocular interactions is not present or, at least, is very much less. A mechanism for matching

Fig. 1 Photographs illustrating eye position at metamorphic climax and subsequently in a, *X. laevis* and b, *R. pipiens*. In each case, the smallest animal is one just at the completion of metamorphosis and the largest is 1 yr or more post-metamorphic. For *X. laevis*, an additional animal aged 4 wk post-metamorphosis is also shown.

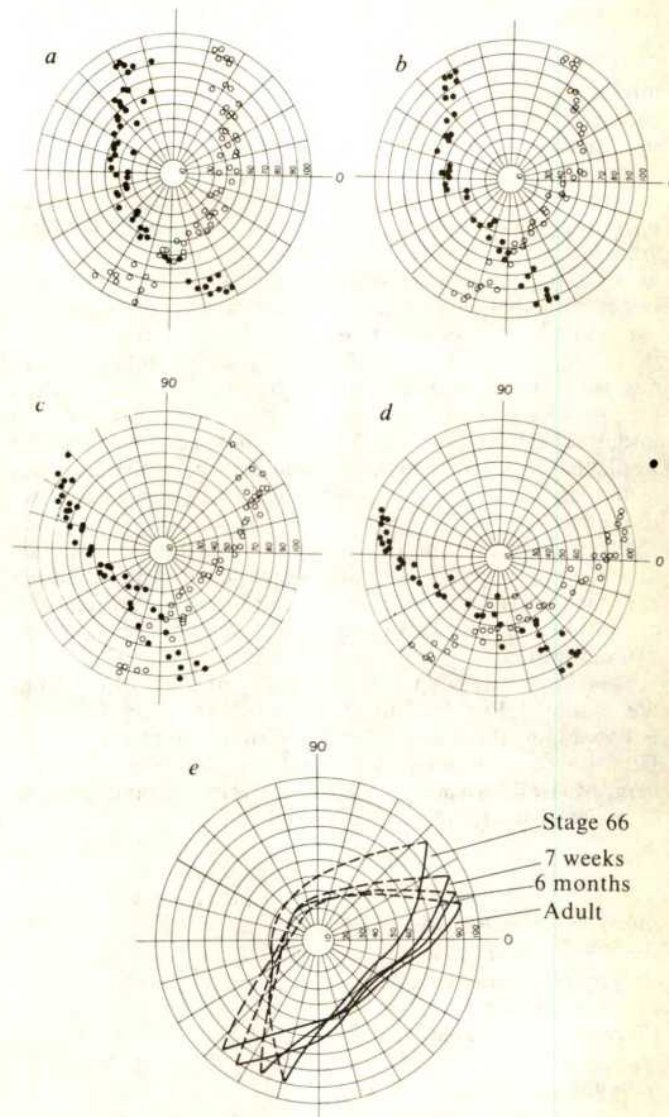

Fig. 2 Visual field boundaries for *R. pipiens* and *X. laevis*. Anterior visual field boundaries for the left (●) and right (○) eyes are shown for metamorphic climax *Rana* (a) and adult *Rana* (b) and for *Xenopus* (c, metamorphic climax; d, adult). Each map represents a hemisphere with the centre raised from the page. The animal should be pictured as sitting inside the hemisphere and facing the reader. The animal's eyes are in the plane of the page and centred on the intersection of planes corresponding to the vertical and horizontal meridia of the map. The symbols are actual border points for several different animals obtained as described in the text. Similar maps obtained for the posterior visual field boundaries are not shown. Data are from five animals in a, c and d and four in b. From maps like these, average visual field boundaries were estimated to illustrate the time course of eye migration in *Xenopus* (e). In (e), the visual field boundary of only the right eye of animals at the indicated ages is shown. The map, however, should this time be interpreted as a complete sphere with the posterior borders of the visual field (broken lines) being seen through the transparent anterior hemisphere.

the ipsilateral to the contralateral visuotectal projections may be correspondingly absent or significantly less effective and hence not lead to the same sequelae to experimental eye rotation as in *Xenopus*. Following this line of argument, our findings not only provide a possible explanation for the discrepant experimental results in *Rana* and *Xenopus* but also support the suggestion of Keating that visual experience is important in assuring proper binocular interaction in conditions of continuing eye migration⁸.

On the other hand, the differences between *Rana* and

Xenopus may be more quantitative than qualitative. In reviewing the mammalian literature, Grobstein and Chow^{10,11} put forward the proposition that binocular interaction may necessarily depend on visual experience because developmental variability makes genetic information inadequate to assure proper pairing of retinal regions. They also suggested that the influence of visual experience is probably constrained to some restricted range of operation by the genetically based developmental program (a suggestion earlier made by Shlaer¹²). It may well be that the range of operation in *Xenopus* is quite large, corresponding to the range of relative eye positions over which the system must operate, whereas in *Rana* it is quite small. Thus, the fairly large eye rotations which are necessary experimentally to be sure that a rotation has been accomplished lead to a compensation of the ipsilateral projections in *Xenopus* but not in *Rana*. It would be of interest to know whether the ipsilateral projection in *Rana* will compensate following very small eye rotations.

After submission of this paper it came to our attention that Keating¹³ has recently also suggested that the differing experimental results in *Rana* and *Xenopus* may relate to quantitative rather than qualitative differences between the two organisms.

Optimal mate selection in the toad *Bufo bufo*

SEXUAL reproduction can no longer be regarded as a cooperative venture in which males and females are selected to achieve the same goals. The optimal reproductive strategy for a male is often very different from that for a female^{1,2}. We report here that, in the wild, toads (*Bufo bufo*) do not pair up at random, that this comes about through male-male competition probably influenced by the behaviour of the female and that mating involves a compromise between different male and female optima.

Toads visit ponds to breed in early spring. All the year's reproductive activity takes place within a few weeks, after which the toads leave the pond and remain on land until the next year³. Our observations were made at a pond near Oxford in March and April 1977. Every female we found in the pond was already in amplexus; that is a male was clasped onto her back, gripping her pectoral girdle with his forearms. Males greatly outnumbered females, however,

and during 11 d we found that $84.9 \pm 9.3\%$ (mean ± 1 s.d.) of the males were unpaired. The excess of males on any one day probably occurred because males can mate more than once and individuals spend most of the breeding season in the pond, whereas females, who can only spawn once, visit the pond for a shorter time. Thus at any particular time most of the male population is in the pond but only a small fraction of the female population^{3,4}.

We measured the snout-vent lengths of males and females we found in amplexus. Before the start of spawning there was no significant correlation between the length of males and females in amplexus (on one day, $r = 0.094$, $n = 32$; on another day, $r = 0.299$, $n = 26$). Small males were just as likely to be paired with large females as were large males. But when we measured the length of pairs actually engaged in spawning, we found a significant relationship ($r = 0.567$, $n = 16$, $P < 0.05$). By the time spawning had started the large females were paired with the large males. This presents two problems; first, what is the mechanism by which this non-random mating comes about and second, what is its functional significance?

What is the mechanism by which non-random mating comes about? In the laboratory we found that even males that were 30 mm smaller than their mates were easily able to maintain amplexus for a week or more. Thus the female herself is apparently unable to displace a male, even if he is very small. In the wild, however, we often found two males tussling over the possession of a female. To investigate the effect of male-male competition we performed a series of experiments in the laboratory, summarised in Fig. 1. The results showed that, just as in the wild, pairing was random at first but after some time large males were more likely to be paired with large females because they could achieve successful takeovers.

We conclude that male-male competition is the mechanism by which the change in pairing from pre-spawning to spawning comes about in the wild. Because it is the female who is in control of locomotion of the pair (her legs are in the most free position for swimming) it seems likely that she will be able to influence whether male-male competition takes place or not. If she has a suitable mate she may swim away from other males in order to avoid interference⁵. If she has been grabbed by an unsuitable male then we suggest that one strategy she could use would be to swim over to where there are other males and thus invite

Fig. 1 Male-male competition experiments in toads. Results of 41 experiments, each with one large male, one small male and a female in a tank. The experiments were done with various absolute sizes but in each, one male was larger than the other male by about 10 mm in body length. *a*, One female (white) and two males (black) are placed in a tank. *b*, Within a few minutes one of the males has paired up with the female. Either male is equally likely to be the first to adopt amplexus. *c*, The unpaired male attacks the pair and attempts to dislodge his rival. The paired male lashes out with his hind legs in defence. *d*, Large males can sometimes displace smaller males but not vice versa ($P < 0.01$).

Fig. 2 Relationship between female body length, measured from snout to vent, and number of eggs laid. Results obtained from pairs spawning in individual tanks in captivity. A sample of 10 of the females was dissected and all had laid their full clutch of eggs. Fitted regression, $y = 67.47x - 3316.68$. A polynomial does not give a significantly better fit than the straight line. Correlation coefficient, $r = 0.669$, $P < 0.001$.

male-male competition. Obviously all this waste of time and energy could be avoided if the female found a suitable mate in the first place. In our laboratory experiments successful takeovers took on average 7 h to complete (mean \pm 1 s.d. = 420.3 ± 321.8 min, $n = 10$). Although we have no evidence for our species, in many anurans the female uses the call of the male as a basis for mate choice⁶. In this context it is interesting that different sized males have different calls so it is possible that a female might select a male of suitable size on the basis of his call⁷.

What is the functional significance of the non-random mating found in the wild? To investigate this question we paired up toads in the laboratory with partners of a size that they would not have mated with in the wild, to see if reproductive success was thereby decreased. We measured reproductive success in terms of the number of fertilised eggs produced. For any given pair this will depend on the number of eggs laid by the female and the percentage of them that are successfully fertilised by the male. Figure 2 shows that, as in other amphibians⁸, the number of eggs laid by a female is related to her size; large females lay more eggs.

As with all cases of external fertilisation, the male has the problem of timing his release of sperm so that it coincides with the female's release of eggs. Precise synchrony of gamete release is presumably important for efficient fertilisation. In many anurans it seems that the stimulus for sperm emission is the passage of the extruding eggs over the venter, cloaca or feet of the male⁹. In some species, just before egg emission, the female arches her back to bring her cloaca in close contact with that of the male⁹.

Figure 3 shows that the degree of matching in size between male and female affects fertilisation success. Where the male is relatively small compared with the female the fertilisation success is lower than where the partners are matched for size. We suggest that the most likely explanation for this relationship is that relatively small males are inefficient at detecting egg release and thus synchronising their timing of emission of sperm. Alternatively where the cloaca of the male is not close to that

of the female, the sperm must have further to swim to reach the eggs and this may decrease fertilisation success.

From the relationship between female length and egg number (Fig. 2) and percentage fertilisation and relative size of male and female (Fig. 3), it is possible to calculate the optimum mate size for a male or female of any given size. To do this we assumed that what will be maximised is the number of fertilised eggs (tadpoles) produced per breeding season. For any given pairing this is simply the number of eggs (calculated from female body length) multiplied by the percentage of these eggs that are successfully fertilised (determined by the relative size of the male and female). To achieve maximum fertilisation of their eggs, females should prefer the largest males. Males, on the other hand, should prefer a different optimum. For any given sized male the number of fertilised eggs increases with female size up to a maximum and then declines. This is because with relatively small females he can achieve efficient fertilisation but small females produce only a few eggs, while at the other extreme, relatively large females lay more eggs but the male can only fertilise a small proportion of them. To maximise the number of fertilised eggs, males should prefer females about 10–20 mm larger than themselves.

Figure 4 shows that there is a conflict between the sexes in the optimal mate size for achieving the maximum number of fertilised eggs. The pairings we observed in the wild mostly fall in between the male optimum and the female optimum. Because females are on average larger than males, the points tend to fall closer to the male optimum. This, however, does not necessarily mean that the males are winning the battle of the sexes. The theoretical optima curves were calculated with the assumption that individuals will be selected to maximise the number of tadpoles produced per year. In long-lived species like toads, however, individuals may be prepared to sacrifice maximal yearly reproduction if by so doing they increase their chance of survival to breed again in future years^{9,10}. Indeed, offspring quantity may be an inappropriate measure of fitness; we have ignored the possible importance of offspring quality (as determined, for

Fig. 3 The effect of relative male and female size (body length, snout to vent) in amplexing pairs of toads on the percentage of the eggs that are successfully fertilised. The smaller the male is relative to the female, the smaller the proportion of fertilised eggs. Pairs of toads were collected from the wild, parted and then formed into new pairs with various sizes of male and female in amplexus. Each pair was kept in a separate tank. The number of fertilised and unfertilised eggs were scored 15 d after egg laying. At this stage the fertilised eggs had developed into small tadpoles, while unfertilised eggs remained as unchanged spheres. None of 100 unchanged eggs examined microscopically from each pair had undergone any cell division. Fitted regression, $y = 104.73x - 52.36$. Correlation coefficient, $r = 0.379$, $P < 0.02$. When the effect of egg number on percentage fertilisation is partialled out, the effect of relative size is still significant ($P < 0.05$). Likewise, it is still significant ($P < 0.02$) when the effect of absolute size of male is partialled out.

Fig. 4 The conflict between males and females in the optimum size of mate assuming that what is maximised is the number of fertilised eggs produced per year. The female line is a minimum because no experimental pairings were done with values greater than 1.1 (for male length divided by female length). If the line in Fig. 3 continued to rise with relatively larger males, then the female optimum curve should be shifted to the left so that larger males are preferred than is indicated. Observed pairings in the wild in the process of spawning (solid circles), fall in between the male and female optima. (Correlation coefficient, $r = 0.567$, $P < 0.05$.)

example, by egg size⁸). Finally we have examined mate selection solely with respect to body size whereas it seems certain that other characters will also influence fitness. In spite of these reservations, as far as we know these data provide the only clear evidence, apart from that from one laboratory study¹¹, that individuals can increase their fertility by non-random choice of mates.

We thank Christopher Perrins and David McFarland for facilities in the Zoology Department at Oxford, J. A. Pye for permission to study at his pond, Ken Marsland and Michael Rayner for help with the experiments, Richard Dawkins and John Krebs for comments on the manuscript and Maggie Norris for typing it.

Use of Ficoll–sodium metrizoate density gradient to separate human X- and Y-bearing spermatozoa

SEVERAL claims have been made about the successful separation of Y-bearing spermatozoa in the past¹. The most recent claim by Ericsson *et al.*² has been disputed^{3,4}. We have attempted to develop a method for separating human X- and Y-bearing spermatozoa, without affecting the motility or the variability of these vital cells. We report here a successful separation of human X- and Y-bearing spermatozoa using a two-step procedure with Ficoll–Sodium metrizoate density gradient. The motility and viability of enriched fractions of spermatozoa was found to be slightly reduced. The reduction was mainly due to centrifugation and not the density gradient. The ability to predetermine the sex of the offspring before conception would have great clinical and sociological significance⁵.

Semen was collected from normal human volunteers. Only samples with a count of over $6 \times 10^7 \text{ ml}^{-1}$ and a motility of at least 50% were used for the experiments. Experiments were performed within 1 h of sample collection.

Ficoll-400 (Pharmacia) and sodium metrizoate (Nyeguard) density gradients were used for the separation. Each semen sample was diluted 20-fold with phosphate buffered saline (PBS), pH 7.2 and centrifuged at 100g for 20 min. The spermatozoa were washed twice with the same buffer, in identical conditions.

In a one-step separation technique the washed spermatozoa were suspended in PBS and made up to the original volume of the semen. The density gradient was prepared by mixing 2.4 ml of 8% Ficoll with 1.0 ml of 32.8% sodium metrizoate. The density of this gradient was 1.08. The spermatozoa suspension was layered on Ficoll–sodium metrizoate density gradient and centrifuged for 20 min at 100g. After centrifugation different layers were separated and suspended in PBS, and the count adjusted to 10^6 ml^{-1} . Smears of these suspensions were stained for the detection of the fluorescent body.

In a two-step separation technique the first step separation was carried out as above. The enriched fractions obtained after the first step were again layered on 15% Ficoll of density 1.04. This was centrifuged for 10 min at 100g. The spermatozoa from the different layers were separated and smears were made for staining.

A modification of the method of Barlow and Vosa⁶ was used for staining the fluorescent body. The smears were air dried, fixed in methanol for 15 min stained by immersing the slides in 0.5% quinacrine hydrochloride (Sigma) for 15 min and washed in running tap water. Excess dye was removed by immersing the slide in PBS at pH 5.6, for 15 min. The slides were mounted in glycerolphosphate buffer (1:9), and examined under oil immersion with dark field condenser of Olympus fluorescent microscope with barrier filter Y-50 and exciter filter B₁. About 10 fields with a minimum of 100 spermatozoa were counted, from each slide, for the presence of the fluorescent body.

After centrifugation with Ficoll–sodium metrizoate it was seen that some of the spermatozoa had settled down and there was a very clear interface which was also rich in spermatozoa. The sediment (S) was rich in Y-bearing spermatozoa, whereas the interface consisted mostly of X spermatozoa (I). The mean percentage of Y-bearing spermatozoa was $43 \pm 2.7\%$ in unseparation (Table 1). The interface contained $74.7 \pm 2.9\%$ X spermatozoa, whereas the percentage in unseparated suspension spermatozoa, whereas the percentage in unseparated suspension was $56.3 \pm 2.7\%$.

In the two-step separation process the percentage of Y-bearing spermatozoa following the initial one-step separation (S₁) was $73.2 \pm 1.0\%$ and this increased only to $76.9 \pm 2.1\%$ after the second separation step (S₂) (Table 2). The results of the one and two step separation procedures with different samples were very consistent. Table 3 shows the percentages of X-spermatozoa before and after two-step separation. The mean percentage of X spermatozoa in the unseparated sample was 54.2 ± 3.2 . The first step procedure

Table 1 Percentages of X- and Y-bearing spermatozoa separated on Ficoll-sodium metrizoate density gradient (1.08) and centrifuged for 20 min

Experiment no.	% Y spermatozoa in washed samples before separation	% Y spermatozoa following separation (S)	% X spermatozoa before separation (I)	% X spermatozoa after separation
1	41.9	70.4	58.1	68.9
2	46.6	70.8	53.4	73.3

Mean \pm s.d.	43.7 \pm 2.7	72.8 \pm 2.2	56.3 \pm 2.7	74.7 \pm 2.9

Spermatozoa were washed twice with PBS pH 7.2 before layering on density gradient.

yielded a fraction containing 74.7 ± 2.9 and the second step 80.6 ± 6.3 of X spermatozoa.

Our results demonstrate that the percentage of Y-bearing spermatozoa in fractions S_1 and S_2 and that of X spermatozoa in fractions I_1 and I_2 are considerably higher than in unseparated samples. It is known that spermatozoa in the semen of normal fertile human males, show considerable heterogeneity⁷. The X- and Y-bearing spermatozoa so separated seemed to be uniform in size and shape in each of the concerned fractions.

it may be assumed that the calculated percentage of the Y-spermatozoa in the one step procedure might be about 82% and in two-step separation it might be as high as 86%.

The Ficoll-sodium metrizoate density gradient has been used extensively for the separation of lymphocytes without any functional damage to cells⁹. Ficoll has also been used for washing spermatozoa¹⁰, and is known not to damage the cells. We have carried out a few experiments to check the motility and viability of spermatozoa following separation. We found that the original

Table 2 Percentage of Y-bearing spermatozoa following two-step separation

Experiment no.	% Y spermatozoa before separation	% Y spermatozoa following one-step separation (S_1)	% Y spermatozoa following two-step separation (S_2)
1	41.9	72.4	80.9
2	45.8	72.7	75.9
3	48.4	73.2	77.9
4	43.0	74.5	77.8
5	41.3	74.2	75.0
6	46.3	71.6	75.0
7	44.2	73.5	76.0
Mean \pm s.d.	44.4 \pm 2.6	73.2 \pm 1.0	76.9 \pm 2.1

The first separation (S_1) was carried out by layering washed spermatozoa on Ficoll-sodium metrizoate gradient of density 1.08. The spermatozoa thus separated were again layered on 15% Ficoll of density 1.04 (S_2).

It is of interest to note that the mean percentage of Y-bearing spermatozoa in semen samples used in the first set of experiments was $43.7 \pm 2.7\%$ and in the second set of experiments $44.4 \pm 2.6\%$. It is generally accepted that 50% of spermatozoa possess Y chromosomes. The lower percentage of Y-bearing spermatozoa observed by us could be due to the fading of fluorescence. It could also be that the ratio was low because of the difficulty of resolving fluorescent body which lies within the dense chromatin⁶. Yet, another reason may be the low uptake of the fluorescent dye by some spermatozoa⁸. If we take all these factors into consideration

motility (85%) was slightly reduced (75%) after the first centrifugation, and motility was further reduced to 58% after another centrifugation with PBS. But, when spermatozoa were layered on Ficoll-sodium metrizoate and centrifuged, motility was 65% and 70% in the interface and the sediment fractions respectively. Thus the gradient has a protective action on the cells, preserving sperm motility. Viability was slightly reduced after two centrifugations, however. This reduction in motility and viability is mainly due to centrifugation and not due to the effect of density gradient. It has been reported¹¹ that following artificial insemination (AI) there

Table 3 Percentage of X-bearing spermatozoa following two-step separation

Experiment no.	% X spermatozoa before separation	% X spermatozoa following one step separation (I_1)	% X spermatozoa following two-step separation (I_2)
1	58.1	77.6	94.4
2	54.2	74.6	80.5
3	51.6	74.2	76.5
4	57.0	74.1	76.6

6	53.7	69.8	77.2
7	55.8	73.5	80.2
Mean \pm s.d.	54.2 \pm 3.2	74.7 \pm 2.9	80.6 \pm 6.3

The first separation (I_1) was carried out by layering washed spermatozoa on Ficoll-sodium metrizoate gradient of density 1.08. Spermatozoa thus separated were again layered on 15% of Ficoll of density 1.04 (I_2).

was an increased number of female offsprings when insemination was carried out 3–4 days before ovulation and an increased probability of males as the ovulation approached. The probability of producing offspring of a desired sex would be enhanced if AI was carried out at the appropriate time¹¹.

Antigen expression on early mouse trophoblast

THE mammalian foetus inherits paternal as well as maternal genes and can be considered to constitute a naturally occurring and highly successful allograft¹. It has been suggested that an important factor in the survival of the foetus in an immunocompetent histoincompatible mother might be the presence of an antigenically deficient barrier of foetal trophoblast cells^{2–4}. Cell surface antigens determined by minor (non-H-2) histocompatibility loci have been demonstrated on cleavage stage mouse embryos⁵, and subsequently major (H-2) as well as non-H-2 determinants have been detected on the trophectoderm of pre-implantation mouse blastocysts^{6,7}. The expression of these antigens, however, is considerably reduced, below detectable levels in the case of H-2, on blastocytes which have been activated for implantation from a state of experimentally induced delay^{6,7}. In addition, immunofluorescence⁸, immunoperoxidase⁷ and mixed haemadsorption (MHA)⁹ studies have failed to demonstrate histocompatibility antigens on the trophoblast component of blastocysts cultured as outgrowths *in vitro*. In contrast to all these findings, however, a recent report has claimed to demonstrate both maternally and paternally inherited antigens on blastocyst outgrowths by means of an MHA technique¹⁰. We have now confirmed this report and reconciled the apparently contradictory results by investigation of the identity of the antigens expressed by the trophoblast at this early stage of its differentiation in four mouse inbred strains.

Blastocysts from spontaneously ovulating females were collected approximately 80 h after mating by flushing the excised uteri with phosphate-buffered saline (PBS). After removal of the zona pellucida by digestion with 0.5% Pronase, embryos were cultured in groups of four or five in the wells of plastic migration plates (Sterilin) under RPMI 1640 medium. MHA tests were performed after 96 h in culture. Blastocyst outgrowths were incubated for 2 h with various dilutions of specific alloantisera either obtained commercially (Searle Diagnostic) or raised between inbred strains of mice by sequential intraperitoneal injections of adult spleen cells. After thorough washing with PBS, a 0.5% suspension of freshly prepared indicator sheep red cells (ISRC)¹¹ was added to the cultures and incubation continued for a further 1 h. Cultures were finally washed in PBS and examined by phase contrast microscopy for adherence of ISRC. Scoring was based on a visual assessment similar to that described by Hausman and Palm¹² and was confirmed by an independent observer. The outgrowths were subsequently fixed in 2.5% glutaraldehyde and stained with

Giemsa as a permanent record. The results are summarised in Table 1.

Although both CBA and C57BL outgrowths showed strongly positive adherence of ISRC after incubations with antisera raised against multiple (H-2+non-H-2) or minor (non-H-2) specificities, no adherence was noted when antisera raised between strains congenic for H-2 were used. The results imply that the reactivity previously reported with these strains¹⁰ is not due to antigens specified by the major histocompatibility complex (MHC). Similar adherence was not observed on A outgrowths when tested with an antiserum against multiple specificities raised in C57BL mice, thus confirming earlier results using this strain combination^{9,13}.

CBA anti-C57BL antiserum detects non-H-2 antigens on B10.BR outgrowths, which is probably a reflection of the common genetic background of the C57BL and B10.BR strains¹⁴, and also detects non-H-2 antigens on A strain trophoblast. Non-H-2 antigens, however, cannot be detected on A outgrowths by either C57BL anti-A or C57BL anti-CBA antisera, even though the latter, adsorbed to remove activity against H-2 antigens, is strongly positive in MHA tests against monolayer cultures of A strain embryonic fibroblasts (unpublished observations). Conversely, the C57BL anti-A antiserum, which is negative for A outgrowths, gives a weakly positive reaction with CBA outgrowths, implying that non-H-2 antigens expressed by adult A strain spleen cells and shared by CBA outgrowths are nevertheless not expressed on A strain trophoblast. This reactivity is unlikely to be a result of shared H-2^k specificities since CBA outgrowths do not react with the congenic anti-H-2^k serum. Since outgrowth from F₁ hybrid blastocysts of reciprocal CBA×A matings continue to express CBA-associated antigens, of both maternal and paternal origin (unpublished observations), and A outgrowths express non-H-2 antigens detected by CBA anti-C57BL antiserum, it is unlikely that any gross masking effect is responsible for the non-expression on A outgrowths of those non-H-2 antigens which are shared by CBA trophoblast and adult A strain tissues. It is therefore clear that H-2 antigens are not expressed on trophoblast at this stage of development and also that there are strain differences in the expression of non-H-2 antigens.

It has been recognised that determinants controlled by the MHC are involved in the interaction of T lymphocytes

Table 1 Detection of cell surface antigens on trophoblast of blastocyst outgrowths by mixed haemadsorption assay (MHA)

Antiserum	Antigens detected	CBA (H-2k)	Target outgrowth C57BL (H-2b)	A (H-2kd)	B10.BR (H-2k)
C57BL anti-CBA	H-2k + non-H-2	+++	—	—	—
CBA anti-C57BL	H-2b + non-H-2	—	+++	++	++
C57BL anti-A	H-2kd + non-H-2	+	—	—	ND
C57BL/10ScSn anti-B10.BR	H-2k	—	—	—	—
B10.BR anti-C57BL/10ScSn	H-2b	—	—	—	—
C57BL anti-CBA (abs)*	non-H-2 only	+++	ND	—	ND

+++ , Heavy adsorption of ISRC on all trophoblast cells. ++ , moderate adsorption of ISRC on > 80% of trophoblast cells. + , light adsorption of ISRC on > 50% of trophoblast cells. — , no adsorption of ISRC. (Occasionally one or two cells in some outgrowths showed strong adsorption. These were very likely of inner cell mass origin.) ND, not determined. Each result is based on observation of not less than 10 outgrowths.

*C57BL anti-CBA antiserum was adsorbed twice against equal volumes of washed B10.BR lymphoid cells. Each adsorption was for 1 h at 37 °C and the resulting serum had no residual activity against H-2k as measured by MHA on B10.BR embryonic fibroblasts.

with non-MHC antigens¹⁵. Lack of reactivity of blastocyst outgrowth trophoblast with antisera which are probably directed against the products of the entire MHC may imply an absence not only of those determinants which are necessary for efferent recognition by cytotoxic T lymphocytes (K and D region determinants)¹⁶ but also of those which are necessary for T-cell sensitisation (the I region associated Ia antigens)¹⁷. Thus the absence of MHC products may enable the trophoblast to fulfil an immunological barrier function because it is unlikely that the expression of non-MHC antigens could render it susceptible to damage by maternal T cells. The possible interplay between these components of the trophoblast cell surface and other types of maternal immune response as well as their potential involvement in developmental interactions with maternal and/or foetal cells is unexplored.

It must be emphasised that these findings relate only to the trophoblast of the blastocyst outgrowth, for the antigenic status of trophoblast is not constant throughout its ontogeny and differentiation^{9,13}. This probably reflects a changing functional role for this tissue in the materno-foetal immunological relationship.

I thank Drs E. J. Jenkinson and W. D. Billington for helpful discussion and advice. The work was initiated during the tenure of a graduate studentship from the MRC and subsequently supported by the Rockefeller Foundation.

Ly-6 is a T-cell differentiation antigen

THERE is ample evidence that membrane antigenic markers change as the cells differentiate along a given pathway. Thus a B cell acquires its receptors, immunoglobulin, as it matures to a functional state. Yet other membrane markers are acquired as cells differentiate from precursor to the activated effector cell stage. For example, the membrane alloantigen Pca-1 is acquired as B cells become antibody-forming cells¹. Another example is the alloantigen Ala-1, presented on activated lymphocytes of both T- and B-cell series, but not on resting cells². Suppressor cells are lysed by anti-Ia antisera³ while their precursors are not⁴, suggesting either the acquisition of Ia antigens on activation, or a change in susceptibility to lysis. This is of interest as the active molecules of suppression, 'suppressor factors', themselves bear Ia antigens⁵. Thus, in this instance there is the acquisition of a membrane marker which is also present in the functional effector molecule. McKenzie and his colleagues recently described a new T-cell alloantigen, Ly-6, which is expressed on the majority of peripheral T cells but only on a small proportion of thymocytes⁶. Using antiserum directed against Ly-6.2 we have published evidence suggesting that this antigen is present on cytotoxic effector cells⁷.

In the work presented here we extend those investigations, showing that while Ly-6 is present on cytotoxic effector cells it is absent from precursor cells, unlike the Ly-1, 2, 3 antigens where precursor cells usually carry the same antigens as effectors⁸. These observations suggest that Ly-6 can be considered as a unique T cell-restricted differentiation antigen that evolves fairly late in the maturation scheme, at least for killer cells.

When various antisera, directed against cell surface allo-antigens were used to phenotype the cytotoxic effector cells (Fig. 1), we found that AKR (Ly-1.2) killer cells express the phenotype Thy-1⁺ Ly-1⁺2⁺3⁺5⁺6⁺, although in other studies using Ly-1.1 positive strains, such as CBA, killer cells bear the phenotype Thy-1⁺ Ly-1⁺2⁺3⁺ (refs 2, 9). To study the phenotype of the precursor cell it was necessary to treat normal spleen cells with the various antisera and complement and then examine the ability of the remaining cells to generate cytotoxic effector cells. The results of three such experiments are shown in Table 1. The data on total activity indicate that the reduction in killing capacity seen in the populations treated with anti-Ly-2.1 or anti-Thy-1.1 is not the result of poor culture viability. It is clear that the phenotype of the killer cell precursor is Thy-1⁺ Ly-1⁺2⁺6⁻ indicating that the alloantigen Ly-6 is either not carried on the precursor cells, or that the amount of antigen present is not sufficient to mediate complement dependent lysis. A third possibility would be that these particular cells are resistant to complement lysis, however, this is unlikely as the cells are susceptible to lysis by other alloantisera of the same titre such as anti-Thy-1 and anti-Ly-2. In two experiments (data not shown) the anti-Ly-6 was used two- and fourfold more concentrated than necessary to have plateau level killing. Results of these assays were similar to those shown. Treatment, however, of normal cell populations using alloantisera at plateau levels of cytotoxicity fails to eliminate

Fig. 1 Treatment of cytotoxic effector cells with various allo-antisera and complement. AKR spleen cells (H-2^k, Thy-1.1, Ly-1.2, Ly-2.1, Ly-5.1, Ly-6.2) at 10×10^6 per ml were incubated with 3×10^6 irradiated (2,000 rad) BALB/c (H-2^d) spleen cells for 6 d in Marbrook tissue culture flasks. The cells were collected and aliquots placed in tubes containing 3×10^6 viable cells. The cells were treated with 0.3 ml of alloantiserum, used at plateau levels of cytotoxicity, for 30 min at 37 °C, washed, and then treated with 0.3 ml complement diluted to 10%, controls included cells treated with media or complement only. The treated cells were then resuspended to 0.5 ml and serially diluted in microtitre plates. Chromium labelled P815 (H-2^d) mastocytoma cells were used as targets, and were added such that the highest killer target ratio was between 20 : 1 and 30 : 1. After initial centrifugation at 200g the assay was incubated for 4 h at 37 °C, centrifuged again, and 100 µl of supernatant aspirated for counting. The % isotope release is calculated as for Table 1. The data are expressed as the mean % isotope release of duplicate values \pm s.e.m. Antisera— α Ly-1.2, Δ ; no addition, \circ ; C', \square ; α Ly-2.1, Δ ; α Ly-6.2, \blacksquare ; α Ly-5.1, \bullet ; α Thy-1.1, \blacklozenge .

Table 1 Effect of pretreatment of normal spleen cells with alloantiserum and complement on ability to generate cytotoxic effector cells

Treatment of normal spleen cells	% Isotope release (total activity)		
	Experiment 1	Experiment 2	Experiment 3
Nil	90±0.5 (1,260)	60±3 (1,020)	70±5 (1,008)
C' alone	83±3.0 (1,162)	58±2 (986)	60±1 (678)
Anti-Ly-1.2+C'	81±2.0 (1,134)	70±4 (1,470)	ND
Anti-Ly-2.1+C'	52±1.0 (899)	20±2 (300)	ND
Anti-Ly-6.2+C'	84±1.0 (1,130)	54±3 (1,080)	57±1 (974)
Anti-Thy-1.1+C'	48±1.0 (614)	18±3 (270)	16±1 (142)

30×10^6 normal AKR spleen cells (H-2^k, Thy-1.1, Ly-1.2, 2.1, 6.2) were treated with various alloantisera, used at plateau levels of cytotoxicity, and rabbit serum, absorbed with mouse spleen cells, as a source of complement. The cells remaining after a two-stage cytotoxicity procedure were adjusted to 10×10^6 cells per ml and incubated with 3×10^6 irradiated (2,000 rad) BALB/c (H-2^d) spleen cells, for 6 d in a Marbrook tissue culture chamber. The cells were collected and tested for their ability to lyse chromium labelled P815 (H-2^d) mastocytoma cells in a 4-h assay. A peak killer target ratio of 20 : 1 was used, with serial dilutions of the effector cells (not shown). The data in each experiment shown for the 20 : 1 ratio are also valid for each of the serial dilutions. The % isotope release was calculated using the formula

$$\% \text{ isotope release} = \frac{\text{Experimental value} - \text{medium background}}{\text{Detergent release} - \text{medium background}} \times 100$$

Total activity = % viable cell yield \times % isotope release at 20 : 1 K:T ratio. Values are mean \pm s.e.m. ND, Not determined.

all of the precursor cells. This is not surprising as the actual precursors are likely to be heterogeneous with regard to the amount of antigen expressed on the cell surface and as some might escape antiserum treatment. This might be expected in the case of weak alloantisera where the effective antibody is in low concentration. An alternative view is that if only a small percentage of precursors escape kill these may still give a surprisingly high response because feedback controls provided by the missing cells are now lacking.

Figure 2 shows the results of experiments in which cytotoxic effector cells were generated from anti-Ly-6.2 treated spleen cells. The killer cells were then retested for phenotype using the various alloantisera. It is clear that the phenotype Thy-1⁺ Ly-1⁺ 2⁺ 6⁺ is identical to killer cells generated from untreated spleen cells. This suggests that only one pathway is open for the maturation of killer cells, and that at least for the allogeneic system, only one type of cytotoxic cell can be generated in that they are all Ly-6⁺. Replicate experiments have given similar results.

Mouse strains used for producing anti-Ly-6.2 also differ at Ala-1, hence a theoretical possibility exists that Ala-1.2

contaminates our anti-Ly-6.2, although the former alloantisera is produced by immunisation with mitogen-activated cells, and the latter with resting spleen and lymph node cells, which should not carry the Ala-1 antigens. The results of an experiment designed to answer this question are shown in Table 2. After five absorptions of anti-Ly-6.2 with 129 mouse spleen cells (Ly-6.2, Ala-1.1) the ability to lyse killer cells was essentially gone indicating that the major cytotoxic activity of anti-Ly-6.2 is directed against that alloantigen, and that any anti-Ala activity present is at best very weak. The reduction of activity in anti-Ly-6 absorbed with CBA spleen cells probably represents some dilution as well as passive absorption, to be expected when multiple absorptions are performed.

In addition to the implications with regard to the diversity of T cells, our findings suggest that Ly-6 is a differentiation antigen for cytotoxic effector cells. Whether this holds true for other functional T cells such as suppressor cells and helper cells is under study. If Ly-6 is a differentiation antigen for effector T cells one might wonder why it is cytotoxic for such a large number of peripheral T cells. It could well be that the majority of peripheral cells are in fact memory cells for helper, suppressor or killer populations awaiting reactivation with antigen and hence might be susceptible to Ly-6 treatment. One might predict that Ly-1⁺ helper cells¹⁰, Ly-2⁺ 3⁺ suppressor cells¹¹ and Ly-1⁺ 2⁺ 3⁺ killer cells¹², will be sensitive to anti-Ly-6.2 in contrast to their precursors.

Fig. 2 Treatment of cytotoxic effector cells generated from anti-Ly-6.2 treated spleen with various alloantisera. 120×10^6 normal AKR (H-2^k, Thy-1.1, Ly-1.2, Ly-2.1, Ly-6.2) spleen cells were treated with anti-Ly-6.2 and complement. The viable cells (10×10^6 per ml) were incubated with 3×10^6 per ml irradiated (2,000 rad) BALB/c (H-2^d) spleen cells for 6 d in Marbrook tissue culture flasks. The cells were collected and aliquots placed in tubes containing 2×10^6 viable cells. Treatment with the various alloantisera and assay for cytotoxic activity were as for Fig. 1. Symbols as in Fig. 1.

**Table 2** Ability of anti-Ly-6.2 to lyse cytotoxic effector cells after absorption with spleen cells from various mouse strains

Alloantiserum	Spleen cell absorption	C'	(Ly-6.2 ⁺ Ala-1.2 ⁺) effector cells	% Isotope release
—	—	—	3×10^6	$52 \pm 5^*$
—	—	+	3×10^6	$53 \pm 1^*$
Anti-Ly-6.2	—	+	3×10^6	1±1
Anti-Ly-6.2	CBA (Ly-6.1, Ala-1.1)	+	3×10^6	30 ± 1
Anti-Ly-6.2	C57BL (Ly-6.2, Ala-1.2)	+	3×10^6	$52 \pm 1^*$
Anti-Ly-6.2	129 (Ly-6.2, Ala-1.1)	+	3×10^6	$44 \pm 1^*$
Anti-Thy-1.1	—	+	3×10^6	1±1

Aliquots of 0.5 ml of a 1/10 dilution of anti-Ly-6.2 were absorbed five times with packed spleen from various mice. Each absorption used 10 volume % packed spleen cells, incubating with the antiserum for 45 min at 37 °C, followed by centrifugation to remove the cells and repeating the process. After the final absorption each serum was incubated with 3×10^6 cytotoxic C57BL (H-2^b, Ly-6.2, Ala-1.2) effector cells for 30 min at 37 °C. The cells were washed and incubated for a further 45 min with 0.5 ml of spleen absorbed rabbit complement diluted to 10%. After washing, the cells were resuspended to equal volumes and serially diluted in microtitre plates. The assay for cytotoxic activity was identical to that described in Fig. 1.

*Indicates that samples are not significantly different ($P > 0.05$).

Regulation of requirements for anchorage-independent growth of Syrian hamster fibroblasts by somatic mutation

THE ability of mammalian cells to form colonies following suspension in semisolid agar, termed 'anchorage independence', is a phenotypic characteristic associated with cells transformed by oncogenic viruses and chemical carcinogens^{1–3}. Because this phenotypic characteristic has been correlated with tumorigenicity^{2–5}, colony formation in semisolid agar is used frequently as a quantitative *in vitro* assay for neoplastic transformation, especially in studies in Syrian hamster cell systems^{4,5}. It is therefore important to understand the molecular and physiological basis of this phenotype. If the expression of this phenotype can be altered by somatic mutation of identifiable genes, information can be gained concerning the mechanism of anchorage-independent growth *in vitro* and its exact relationship to tumorigenicity and malignancy *in vivo*. We have investigated the ability of cells of the highly tumorigenic Syrian hamster fibroblast line, BP6T (ref. 9) to form colonies when suspended in semisolid agar. Cells of this line produce fibrosarcomas in 100% of newborn Syrian hamster inoculated with ten cells. In addition to anchorage-independent growth, BP6T cells also exhibit other *in vitro* characteristics of neoplastic transformed cell lines, such as increased plating efficiency in liquid medium at low cell densities, and enhanced fibrinolytic activity⁶. In this communication, we report that the ability of this Syrian hamster line to form colonies in semisolid agar is dependent on its utilisation of exogenous purines by way of the hypoxanthine phosphoribosyltransferase (HPRT, E.C.2.4.2.8.)- and adenine phosphoribosyltransferase (APRT, E.C.2.4.2.7.)-mediated salvage pathways. Furthermore, this anchorage-independent property can be inhibited by a somatic mutation at the HPRT locus.

Supplementation of semisolid agar medium with either bactopectone or bactotryptose is a routine procedure when semisolid agar is used as a test medium for anchorage-independent growth^{1–6}. We found that in the absence of bactopectone, the ability of BP6T to produce colonies in semisolid agar was greatly influenced by the density at which the cells were suspended in the agar-containing

medium. At plating densities of less than 10⁴ cells per plate, colony formation was less than 0.1%. As shown in Table 1, however, supplementation of the agar suspension with 0.12% bactopectone permitted a colony-forming efficiency of 80% when 10–100 total cells were plated in each dish. With bactopectone, when the plating inoculum was increased above 10² cells, the efficiency of colony formation declined, decreasing to a value of approximately 30% at an inoculum of 10³ cells (Table 1). This reduction in the efficiency of colony formation with increasing cell density may have resulted both from the convergence of colonies and the competition for growth factors contained in the foetal calf serum and bactopectone supplements.

Since bactopectone has been reported to contain both hypoxanthine, and the unusual purine, 6,8-dihydroxy-purine^{12,13}, we examined the ability of hypoxanthine and other purines to replace the bactopectone requirement. Table 2 demonstrates that hypoxanthine (4 × 10⁻⁵ M) was effective in permitting colony-forming efficiency of 30–42%, whereas guanine (4 × 10⁻⁵ M), was only partially effective, giving a colony-forming efficiency of approximately 20%. Xanthine, which is an inefficient substrate for hamster HPRT (ref. 7), did not support colony formation in agar. These results indicated that hypoxanthine or guanine could replace the bactopectone requirement for efficient colony formation in semisolid agar.

Since the utilisation of hypoxanthine and guanine is catalysed by the salvage enzyme HPRT, we examined the ability of several independently isolated HPRT-deficient strains of BP6T to form colonies in bactopectone-supplemented agar. Three spontaneously occurring (subclones 1–3) and three *N*-methyl-*N'*-nitro-*N*-nitrosoguanidine-induced (subclones 4–6) HPRT-deficient colonies were isolated from BP6T following independent selections in 1–5 µg ml⁻¹ 6-thioguanine. Each of these subclones of BP6T contained less than 1% of the parental HPRT activity, as assayed by the ability of intact cells to incorporate ¹⁴C-hypoxanthine into an acid-precipitable form¹⁰. Moreover, these strains maintained their HPRT-deficient phenotype for at least 40–50 population doublings in the absence of 6-thioguanine, with a reversion frequency less

Table 1 Effect of cell density and bactopectone supplement on colony formation efficiency in semisolid agar

Condition	BP6T cell number seeded	Colony number	Colony formation efficiency
With bactopectone 0.12%	10	9	90
	100	80	80
	200	103	50
	500	186	37
	1,000	260	26
Without bactopectone	100	0	0
	1,000	0	0
	10,000	> 300	> 3

The cell culture medium used was IBR modified Dulbecco's Eagle reinforced medium (ERM) (Biolabs, Northbrook, Illinois) supplemented with 0.22 g% NaHCO₃ and 10% Reheatin F.S. foetal bovine serum (RFS) (Reheis Chemical, Kankakee, Illinois) without antimicrobial agents. Cells were transferred by a gentle trypsinisation with 0.1% trypsin solution (1:250, Gibco, Grand Island, New York) for 5 min at 36.5 °C. Agar cultures contained 3 ml base agar (0.6% agar dissolved in the above tissue culture medium) and 4 ml semisolid agar (0.3–0.4% agar dissolved tissue culture medium) in 35-mm or 60-mm diameter plastic Petri dishes. Before suspension in agar, cells were trypsinised and diluted into tissue culture medium. The cell number in the suspension was counted using a Coulter counter; a pre-determined number of cells was then suspended in the semisolid agar solution at temperatures between 37 and 40 °C, and the agar solution poured just before solidification. Agar cultures were incubated in a 37 °C incubator in a 5% CO₂ atmosphere at 90% relative humidity. At the end of 12–14 d, the number of colonies was counted under a light microscope. Each assay condition was measured in triplicate and the averaged results reported.

Table 2 Effect of purines on colony formation efficiency in semisolid agar by wild-type HPRT⁺ strains of BP6T cells

Cell strain	Agar supplement	Cell number seeded	Colony number	Colony formation efficiency (%)
BP6T (wild-type)	None	1,000	0	0
	Hypoxanthine 4×10^{-5} M	250	106	42
	Hypoxanthine 4×10^{-5} M	600	223	37
	Hypoxanthine 4×10^{-5} M	1,000	> 300	> 30
	Guanine 4×10^{-5} M	500	96	19
	Guanine 4×10^{-5} M	1,000	212	21
	Xanthine 4×10^{-5} M	500	0	0
	Xanthine 4×10^{-5} M	1,000	2	< 1
	Adenine 4×10^{-5} M	500	234	47
	Adenine 4×10^{-5} M	1,000	300	> 30
BP6T subclone 4 (HPRT ⁻)	Bactopeptone 0.12%	500	0	0
	Bactopeptone 0.12%	1,000	0	0
	Hypoxanthine 4×10^{-5} M	500	0	0
	Hypoxanthine 4×10^{-5} M	1,000	0	0
	Adenine 4×10^{-5} M	500	159	32
	Adenine 4×10^{-5} M	1,000	254	25
*BP6T subclone 5 (HPRT ⁻)	Bactopeptone 0.12%	550	0	0
	Bactopeptone 0.12%	1,000	< 1	< 1
	Bactopeptone 0.12%			
	+ adenine 4×10^{-5} M	550	142	26
	+ adenine 4×10^{-5} M	1,000	268	27

than 2×10^{-7} (as measured by their sensitivity to medium containing hypoxanthine $13.6 \mu\text{g ml}^{-1}$, amethopterin $0.19 \mu\text{g ml}^{-1}$ and thymidine $3.9 \mu\text{g ml}^{-1}$ (ref. 11).

The ability of these HPRT-deficient strains of BP6T to form colonies in bactopeptone-supplemented agar (Table 3) was either greatly diminished or totally lacking at

colonies (subclones 2, 3 and 6). This represents minimally a 50–300-fold decrease in colony-forming efficiency in the HPRT-deficient strains compared with the wild-type BP6T strain.

When the wild-type BP6T and the HPRT-deficient strains were assayed by the same procedure¹⁰ for ¹⁴C-adenine incorporation by way of the APRT pathway, all the HPRT-deficient strains incorporated adenine into acid-precipitable material at a level comparable with the parental BP6T wild-type strain. This result indicated that the HPRT-deficient strains possessed a functional adenine salvage pathway. Since HPRT-deficient strains of BP6T cells retained the ability to salvage adenine and consequently the ability to convert AMP to other purine nucleotides (IMP and GMP), we examined the ability of adenine to support colony formation by these deficient cells in bactopeptone-supplemented agar. Table 2 shows that HPRT-deficient strains (subclones 4 and 5), which did not form colonies in semisolid agar supplemented with either bactopeptone or hypoxanthine, regained the ability to form colonies in agar at 24–34% efficiency after the addition of adenine 4×10^{-5} M). Adenine was also found to support colony formation by the wild-type BP6T strain in unsupplemented agar, as a replacement for bactopeptone (Table 2).

These results indicate that the malignant Syrian hamster fibroblast cell line, BP6T, requires exogenous purines and appropriate functional salvage enzymes to form colonies efficiently in semisolid agar. Other *in vitro* properties of this cell line, such as cloning efficiency in liquid medium and enhanced fibrinolytic activity were essentially

Table 3 Effect of HPRT deficiency on colony formation in semisolid agar*

BP6T strain	Cell number seeded	Colony number	Colony formation efficiency %
BP6T (wild type)	200	103	50
	500	186	37
	1,000	260	26
BP6T subclone 1 (HPRT ⁻)	500	0	0
BP6T subclone 2 (HPRT ⁻)	550	6	1
BP6T subclone 3 (HPRT ⁻)	500	3	< 1
BP6T subclone 4 (HPRT ⁻)	1,000	1	< 1
BP6T subclone 5 (HPRT ⁻)	1,000	1	< 1
BP6T subclone 6 (HPRT ⁻)	1,000	11	1

* The semisolid agar media were all supplemented with bactopeptone, 0.12%.

plating densities of less than 10^4 cells. After 14 d incubation, 200–500 BP6T cells produced colonies at an efficiency of 30–50% (Table 3), whereas 500–1,000 HPRT-deficient cells from six individual clones produced either one or no colonies (subclones 1, 4 and 5) or from three to eleven

Table 4 Summary of *in vitro* properties of Syrian hamster cell lines

Cell type	Genotype	CE*	Fibrinolysis†	Colony-forming efficiency‡ in semisolid agar	Tumorigenicity§
Syrian hamster embryo cells	HPRT ⁺	2–6%	(–)	0%	–
BP6T	HPRT ⁺	80%	+	50–80%	+
BP6T subclone 5	HPRT ⁻	41%	+	< 1%	+
BP6T subclone 6	HPRT ⁻	61%	+	1%	ND

* CE is cloning efficiency in liquid medium.

† Fibrinolytic activity was measured both in the extracellular medium and in cell lysates by procedures described previously⁹.

‡ The semisolid agar media were supplemented with 0.12% bactopeptone only. Values for the BP6T derivatives were taken from Table 3. Syrian hamster embryo cells exhibited no colonies when 10^6 cells were tested.

§ Tumorigenicity was measured by subcutaneously injecting 0.1 ml complete medium containing varying concentrations of cells into non-immunosuppressed neonatal littermates (1–3-d-old) of outbred Syrian hamsters (Lakeview). Injection of 10^7 Syrian hamster embryo cells produced no tumours, whereas injection of 10^2 cells of BP6T and BP6T subclone 5 produced tumours.

unaltered by the forward mutation at the HPRT locus (Table 4). Additionally, the population-doubling times and cell saturation densities were unchanged (data not shown). It would be interesting to revert HPRT-deficient strains to HPRT⁺ to see if growth in agar supplemented only with hypoxanthine is regained. To date, however, attempts to isolate HPRT⁺ revertants of these strains have been unsuccessful.

Previous studies have shown that virally transformed derivatives of BHK 21 clone 13 (an established cell line of Syrian hamster origin) also require exogenous purines to support colony formation in agar, although not in liquid medium^{6,7}. Furthermore, 'normal' BHK cells (which induce tumours with high numbers of injected cells⁴) can be stimulated to form colonies in semisolid agar if thymidine is supplied in addition to the required purine supplement⁸. In contrast to our findings with BP6T, we observed no dependence on purines or purine salvage enzymes for anchorage-independent growth by HPRT- and APRT-deficient mouse fibroblast strains (data not shown). This finding suggests that *in vitro* requirements for anchorage-independent growth may vary between cells of different species origin.

Recently, stable variants which have lost certain *in vitro* phenotypes often associated with neoplasia have been isolated after treatment with mutagens^{4,14,15}. Such studies frequently rely on assumed correlations between demonstrated cellular alterations *in vitro* and tumorigenicity *in vivo*. Our results demonstrate that somatic mutation in tumorigenic Syrian hamster cells can lead to altered anchorage requirements for cellular growth, although the tumorigenic potential of these cells need not be lost (Table 4). Therefore, alterations in requirements for anchorage-independent growth *in vitro* may not necessarily correlate with malignancy.

Rapid induction of amphotericin B sensitivity in L1210 leukaemia cells by liposomes containing ergosterol

AMPHOTERICIN B is a polyene antibiotic whose clinical use has been limited to the treatment of fungal infections. The mode of action of amphotericin B is believed to involve damage to cell membranes containing certain sterols^{1,2}. One sterol of primary importance for this membrane interaction is ergosterol³⁻⁵, and it is believed that its presence in

cell membranes of fungi confers sensitivity to amphotericin B². Studies with phospholipid vesicles indicate that it is possible to alter the lipid content of cultured mammalian cells after short incubations with liposomes of defined content^{6,7}. We report here that brief treatment with liposomes containing ergosterol can sensitise L1210 murine leukaemia cells to the subsequent action of amphotericin B.

Liposomes containing sterol were prepared using methods described by Weissmann⁸ and Cooper⁹. Egg yolk lecithin (EYL, Sigma) 40 mg alone or EYL 40 mg and ergosterol (Sigma) 80 mg, were dissolved in chloroform to assure complete mixing. The mixture of sterol and phospholipid was taken to dryness under nitrogen and 10 ml of buffer (100 mM NaCl, 15 mM KCl, 5 mM TES (N-Tris[hydroxymethyl]methyl-2-aminoethane sulphonic acid), 10 mM dextrose, 0.1 mM EDTA; pH 7.4) were added. This mixture was sonicated in a Branson Sonifier (Heat Systems Inc.), at an output setting of 60 W in a nitrogen atmosphere for 1 h at 3 °C. After sonication, the suspension was centrifuged at 30,000g for 10 min to remove non-dispersed lipids. Final phospholipid concentration was measured by the method of Bartlett¹⁰. Final ergosterol concentration was determined by the cholesterol method of Rudel and Morris¹¹, using ergosterol for the standard curve. Before incubation with cells, liposomes were diluted with buffer and medium to yield a final phospholipid concentration of 0.4 mg ml⁻¹ and a final ergosterol concentration of 0.05 mg ml⁻¹. Thin layer chromatography of the liposome preparation revealed the expected amount of phospholipid and sterol with less than 2% lysophosphatidylcholine contamination.

L1210 mouse leukaemia cells which had been in stationary phase for 5 h were adjusted to 7×10^5 cells per ml with fresh medium. Aliquots of this suspension were placed in 75-cm² Falcon flasks, to which (1) buffer without liposomes, (2) EYL liposomes in buffer, or (3) EYL liposomes containing ergosterol in buffer, were added to yield a final cell concentration of 5.5×10^5 per ml. Cells were incubated for 1 h at 37 °C, collected by centrifugation at 300 g for 5 min, and washed twice with fresh medium. They were resuspended at 1×10^5 cells per ml in fresh medium (10 ml) containing amphotericin B or the solvent, DMSO, in 25 cm² Corning flasks. Cells were incubated for 2 h at 37 °C, washed twice more and resuspended in fresh medium.

After treatment and washing, one or more of the following techniques were used to assess cell survival. (1) Cell number was determined immediately after incubation in medium containing amphotericin B. (2) Trypan blue exclusion—washed cells in 0.5 ml medium were mixed with 0.1 ml 0.4% trypan blue in normal saline—after 5 min, 200 cells were counted and the number of cells excluding stain determined. (3) Cell number was determined after resuspension in fresh medium and 45 h additional incubation at 37 °C.

L1210 cells which were first incubated for 1 h with EYL liposomes containing ergosterol, and then treated for 2 h with amphotericin B at concentrations of 4–8 µg ml⁻¹ were reduced in number when counted immediately after the incubation period with amphotericin B (Fig. 1). These cell populations were unable to exclude Trypan blue effectively (Table 1), and phase microscopic examination revealed many cells undergoing lysis and much cellular debris. Treatment of cells with buffer alone or EYL liposomes without ergosterol did not confer such sensitivity to the action of amphotericin B.

Cells first treated with EYL liposomes containing ergosterol, exposed to amphotericin B, then incubated without ergosterol or amphotericin B for a further 45 h, exhibited growth inhibition and/or continuing diminution of cell number (Fig. 1). This effect was dose dependent over an amphotericin B concentration range of 2–8 µg ml⁻¹. Liposome treatment without subsequent amphotericin B

exposure was without effect. Amphotericin B treatment of cell populations previously incubated with buffer or EYL liposomes did not result in such reduction in cell number after 45 h further incubation (Fig. 1).

All cell populations examined immediately after the 1-h incubation period with buffer or liposome preparations excluded Trypan blue effectively. There was no change in cell number when these populations were compared with untreated cells. No cells were found adherent to vessel surfaces.

We have demonstrated that brief exposure to liposomes containing ergosterol can confer amphotericin sensitivity to one type of murine leukaemia cell. Other workers have demonstrated that *Tetrahymena pyriformis* cells grown for 36–40 h in culture medium containing ergosterol will incorporate ergosterol into their cell membranes and then become sensitive to the action of amphotericin B⁴. In an earlier communication¹² it was reported that 22 h of growth in culture medium containing ergosterol was required for L1210 cells to become markedly affected by amphotericin B.

The mechanisms of ergosterol and amphotericin B action are not fully understood. Ergosterol may nonspecifically prepare the cell membrane for optimum interaction with amphotericin B by making the membrane more rigid or ordered¹³. Alternatively ergosterol could uniquely combine with amphotericin B and change membrane configuration so that membrane disruption occurs and cell lysis ensues^{14,15}.

Liposomes have been shown to interact with a variety of mammalian cell types^{7,8}. Although the precise nature of the interaction is not clear, the liposomes can transfer large amounts of lipids to cells and alter cellular lipid content⁶. Since sensitisation to amphotericin B might require the presence of a specific sterol at the membrane level, we presume that sensitisation observed after treat-

Fig. 1 Time course of effect of amphotericin B on cell number. L1210 cells (from Dr V. Bono Jr, NCI) were incubated for 1 h in the buffer, EYL liposomes or EYL liposomes containing ergosterol. Cells were washed, treated for 2 h with amphotericin B or dimethylsulphoxide (DMSO), then washed again. One aliquot of cells was counted and another was resuspended in fresh medium and incubated for a further 45 h and then counted. Cells treated with EYL liposomes containing ergosterol followed by treatment with DMSO (Δ), or amphotericin B at $2 \mu\text{g ml}^{-1}$ (\diamond), $4 \mu\text{g ml}^{-1}$ (\square), $6 \mu\text{g ml}^{-1}$ (\circ) or $8 \mu\text{g ml}^{-1}$ (\bullet). Cells treated with EYL liposomes then amphotericin B $6 \mu\text{g ml}^{-1}$ (\blacksquare); cells treated with buffer (without any liposomes) then amphotericin B $6 \mu\text{g ml}^{-1}$ (\blacktriangle). RPMI 1630 medium was from NIH Media Unit. In all experiments media were supplemented with 20% foetal calf serum (Flow) and gentamicin $40 \mu\text{g ml}^{-1}$ (Schering). Foetal calf serum was heat inactivated at 56°C for 30 min. Cell number was estimated with a Coulter Counter. Amphotericin B (Calbiochem) was freshly prepared in DMSO to give a 20 mg ml^{-1} stock solution. The DMSO concentration in incubation mixtures did not exceed 0.1% (v/v).

Table 1 Effect of treatment with liposomes containing ergosterol on Trypan blue exclusion

Amphotericin B ($\mu\text{g ml}^{-1}$)	Cells excluding Trypan blue (% of buffer control)	
	EYL liposomes containing ergosterol	EYL liposomes alone
0	94	94
2	73	85
4	44	78
6	15	85

L1210 cells were incubated for 1 h with buffer, EYL liposomes or EYL liposomes containing ergosterol. Cells were washed, treated for 2 h with amphotericin B, washed again, and resuspended in fresh medium. 0.5 ml of cells in fresh medium was mixed with 0.1 ml 0.4% Trypan blue in normal saline. After 5 min, 200 cells were counted and number excluding trypan blue determined.

ment with liposomes containing ergosterol was due to addition of this specific sterol to the membrane region.

As drug carriers, liposomes offer several advantages over conventional modes of drug administration. It has been suggested that they can transport high concentrations of otherwise toxic agents and perhaps can be directed to selected tissue targets^{16–19}. Our data indicate that in addition, specifically constituted liposomes may sensitise certain cell types to chemotherapeutic agents to which they were previously resistant. This study demonstrates a novel use of liposomes for the purpose of functionally altering the membranes of mammalian cells.

We thank Dr Marco Rabinovitz for his guidance and support, Ms Joyce Fisher for her technical assistance, and Ms Sylvia Rose and Ms Charlotte Thomas for secretarial help.

Prostaglandin endoperoxides and thromboxane A₂ can induce platelet aggregation in the absence of secretion

PLATELET aggregation and secretion are widely studied not only because they are believed to reflect the major *in vivo* platelet function, formation of the primary haemostatic plug, but also because they involve fundamental cellular regulatory mechanisms. The synthesis of biologically active prostaglandin (PG) intermediates (endoperoxides and thromboxanes) seems to be an important step in the

regulation of platelet function^{1,2}, but the physiological roles and mechanism(s) of these compounds are unknown. It is claimed by Malmsten *et al.*³ and Samuelsson *et al.*⁴ that PG endoperoxides and thromboxane A₂ cause platelet aggregation only by inducing platelets to secrete ADP that in turn causes aggregation. In view of observations that platelets deficient in releasable ADP (storage pool-deficient platelets or platelets depleted of storage granules) still aggregate in response to arachidonic acid⁵⁻⁷, the precursor of the intermediates, the validity of this claim has been open to question. We have investigated platelet stimulation by PG endoperoxides (PGG₂ and PGH₂), an endoperoxide analogue ((15S)-hydroxy-11 α , 9 α -(epoxy-methano) prosta-5Z, 13E-dienoic acid; U-46619), thromboxane A₂-like material and arachidonic acid, using a new instrument that simultaneously monitors aggregation and secretion in the same platelet suspension⁸, permitting careful analysis of the relationships between aggregation and secretion. We report here that although high concentrations of the endoperoxide analogue, the natural endoperoxides and thromboxane A₂ induce both platelet aggregation and secretion, low concentrations cause aggregation without detectable secretion.

Secretion was monitored by recording luminescence resulting from the interaction of released ATP (secreted simultaneously with ADP) with firefly luciferase and

Fig. 1 Simultaneous recording of aggregation and secretion induced by (a) PG endoperoxide analogue (U-46619), (b and c) natural endoperoxides (PGH₂ and PGG₂) and (d) thromboxane A₂ added to stirred platelet-rich plasma. These experiments represent typical results obtained with low, intermediate and saturating (maximal aggregation and secretion of ATP) concentrations of each stimulus. Secretion of ATP (lower traces) was measured by the firefly luminescence assay, with the gain of the instrument set so that maximum release with a high concentration of thrombin gave half-chart deflection (max), which corresponds to about 5 μ M ATP or 1 nmol per 10⁸ platelets. In the three experiments where the lowest concentrations of the analogue, PGH₂ or PGG₂ were added, the gain was doubled to detect even trace secretion of ATP. The sensitivity of the measurement in these conditions is such that a pen deflection of twice the noise amplitude is caused by less than 50 nM ATP. Since others^{19,10} have shown that ATP and ADP are secreted in parallel with the ATP/ADP ratio between 0.5 and 1.0, we would detect secretion of 0.1 μ M ADP. The decrease in the signal seen at the end of some curves does not represent uptake or metabolism of ATP by platelets, but is due to the well-known property of the assay system to show a decay in luminescence^{21,22}. Aggregation (upper traces) was measured simultaneously in the same cuvette, with the limit set with platelet-free plasma (PFP) as indicated. Reactions were initiated by addition of the stimulating agents to stirred platelet-rich plasma, except for experiments with PGH₂ and PGG₂, where the reaction was initiated by addition of platelet-rich plasma to a cuvette to which the endoperoxide had previously been added and the solvent (acetone) evaporated with a gentle stream of nitrogen. Thromboxane A₂-like material was generated by incubation of dog platelet-rich plasma with 0.5 mM arachidonic acid, as described by Chignard and Vargaftig¹². Aliquots of the dog platelet-rich plasma containing thromboxane A₂-like material were transferred directly to human platelet-rich plasma that had been pre-incubated with indomethacin (15 μ M for 30 s) to prevent stimulation by arachidonic acid. The concentration of thromboxane A₂-like material was varied by transferring different volumes or by varying the time of incubation with arachidonic acid. Control dog platelet-rich plasma had no effect on human platelets, and we confirmed the observations of Chignard and Vargaftig¹² that dog platelets neither aggregate nor secrete in response to arachidonic acid, although they do metabolise arachidonic acid to PGs and thromboxanes. All experiments were carried out with the cell compartment at 37°C, and the chart speed was 60 s inch⁻¹ (time bar in top trace). Each experiment was carried out on platelet-rich plasma (counts not standardised) from at least three donors. Although there were some quantitative differences between donors, the pattern of responses was consistent and the data shown are from a single donor, so that comparisons between stimuli are valid. The concentrations of stimuli (for low, intermediate and high concentrations) were: endoperoxide analogue 0.5, 1.2 and 2.2 μ M; PGH₂ 0.5, 0.8 and 9.4 μ M; PGG₂ 0.3, 0.5 and 2.8 μ M. Exact concentrations of thromboxane A₂-like material were not determined.

luciferin as described previously^{9,10}. The reaction was carried out in a new cell compartment designed to permit simultaneous measurement of platelet aggregation and secretion. Details of this technique have been described previously⁸. PGG₂ and PGH₂ were prepared essentially as described elsewhere¹¹. Final concentrations quoted are based on the specific activity of the radioactive arachidonic acid used in their biosynthesis. Thromboxane A₂-like material was generated by incubation of dog platelet-rich plasma with arachidonic acid¹². Although dog platelets do not aggregate or secrete nucleotides or other contents of dense bodies in response to arachidonic acid, they do synthesise PG endoperoxides and thromboxane A₂, which will aggregate human platelets. Since Smith *et al.*¹³ have shown that in the conditions used (incubation in plasma at 37 °C), thromboxane A₂ activity persists after complete disappearance of the endoperoxides, we refer to the active component as thromboxane A₂. Human platelet-rich plasma, prepared from whole blood collected in 0.1 volume 3.8% sodium citrate¹⁴, was kept at room temperature and was used within 3 h. Experiments were at 37 °C. All donors denied taking any drug for at least 10 d before venipuncture.

The effects of the unstable PG intermediates and the stable endoperoxide analogue on platelets were observed by recording the precise temporal relationships of aggregation and secretion (Fig. 1). Each compound was tested over a range of concentrations from an amount just sufficient to cause an observed effect to an amount greater than that required for the maximal effect. Individual donors varied in their responsiveness to the endoperoxides, but PGG₂ was consistently more potent than PGH₂. Examples of typical results for low, intermediate and saturating concentrations of each compound are shown in Fig. 1.

At low concentrations, each compound induced aggregation in the complete absence of detectable secretion (that is, primary aggregation), directly refuting the claim^{3,4} that the endoperoxides induce platelet aggregation only through release of ADP.

At intermediate concentrations, some difference was observed between the stable endoperoxide analogue and the unstable PG intermediates. The analogue induced biphasic aggregation, with secretion beginning only after a long lag and in parallel with the second wave of aggregation. This is characteristic of the response of platelets to other primary aggregating agents such as ADP and adrenaline^{14,15}. In contrast, when the stimulating agent was PGH₂ or PGG₂ we never observed biphasic aggregation or a long lag before secretion; instead intermediate concentrations of these compounds have consistently induced completely reversible aggregation accompanied by secretion. (Such readily reversible aggregation in platelets undergoing secretion is unusual.) This difference indicates that the synthetic endoperoxide analogue may not exactly mimic the platelet stimulating properties of the natural endoperoxides. Thromboxane A₂-like material induced aggregation and secretion with a temporal relationship similar to that for the naturally occurring endoperoxides.

Addition of increasingly higher concentrations of each stimulus resulted in more rapid and extensive aggregation-secretion curves until a maximal response was attained. In the case of maximal response, aggregation and secretion proceeded as temporally parallel events. With each stimulus, the secretion curves resulting from high concentrations of PGG₂ were nearly identical to those obtained previously with other potent stimuli (for example, thrombin or A23187) (ref. 15), with no evidence of the extremely fast secretion reported by Malmsten¹⁶ and Corey *et al.*¹⁷, who observed complete release within 5 s.

Arachidonic acid also induced aggregation and secretion, probably because it is the substrate for PG and thromboxane synthesis¹⁸. Arachidonic acid differed from the other compounds tested in that aggregation was always

Fig. 2 Simultaneous recording of aggregation and secretion induced by arachidonic acid. The experiments were as described in Fig. 1. The fourth trace was done in the absence of stirring. Note that the higher concentrations of arachidonic acid lead to progressively shorter lag times and more rapid kinetics of secretion, but the total ATP secreted does not increase significantly. Lower concentrations of arachidonic acid also induced aggregation and secretion in parallel, with increasingly longer lags, until a threshold concentration was reached below which there was neither aggregation nor secretion (approximately 100 μM in the experiment shown). Sodium arachidonate concentrations (from left to right): 110, 190, 640, 640 μM.

accompanied by secretion (Fig. 2). (This is not inconsistent with a report⁵ that arachidonic acid causes aggregation of platelets that have been depleted of their secretory granules by treatment with thrombin, but suggests that aggregation and secretion may be independent, parallel responses of platelet activation¹⁵.) This difference in activity of the PG intermediates and arachidonic acid suggests that there may be a difference between the effects of extracellular intermediates and the same compounds generated intracellularly. That is, primary aggregation may be due to interactions of the intermediates with the outer membrane, whereas activation by arachidonic acid may involve an intracellular action of the same intermediates.

We also observed that at higher concentrations, each stimulus, as shown in Fig. 2 for arachidonic acid, is able to induce secretion in the virtual absence of aggregation (unstirred suspension), indicating that secretion is not dependent on aggregation, as shown for other stimuli, such as thrombin¹⁵.

We conclude that endoperoxides and thromboxane A₂ can induce aggregation without secretion of nucleotides, that higher concentrations of endoperoxides and thromboxanes can induce secretion independent of aggregation, and that human platelet aggregation can spontaneously reverse even when accompanied by secretion. This is the first direct evidence that PG intermediates can cause primary aggregation of normal human platelets.

New polymorphism of platelet membrane glycoproteins

THE surface of the human blood platelet is rich in carbohydrate and at least four glycoprotein components have been resolved by gel electrophoresis of isolated platelet plasma membranes¹. Two platelet disease states are characterised by a diminution or absence of certain of these glycoproteins²⁻⁵: in the case of Bernard-Soulier disease, glycoprotein I (molecular weight (MW) 150,000) is lacking while platelet membranes isolated from patients suffering from Glanzmann's thrombasthenia lack glycoprotein II (MW 120,000). While screening several patients with ill-defined but clinically evident haemostatic problems, we have now identified two unrelated individuals who show an abnormal polymorphic pattern of glycoprotein distribution within their platelet membranes and a concomitant reduction in the ability of the intact platelets to bind thrombin.

Polyacrylamide gel electrophoresis of normal platelet plasma membranes gives a pattern of four major bands which stain with the periodate-Schiff reagent¹ (Fig. 1a). These bands have been designated glycoproteins I, II, III and IV and have electrophoretic mobilities corresponding to molecular weights of 150,000, 120,000, 98,000 and 87,000, respectively. These four peaks are in the ratio of 55:28:6:11, averaged from 37 samples, and show no age or sex-related differences.

In the case of platelets from two individuals identified

Fig. 1 Glycoprotein patterns from normal (a) and abnormal (b) platelets. A platelet membrane fraction was subjected to polyacrylamide gel electrophoresis in the presence of sodium dodecyl sulphate and β -mercaptoethanol followed by staining with periodate-Schiff reagent, as previously described¹.

Fig. 2 Thrombin binding to normal and abnormal platelets. Control, \circ : patient 1, Δ : patient 2, \bullet . Binding studies were performed by the Majerus technique using cacodylate buffer¹² and highly purified human thrombin¹⁴ (2,850 NIH units mg^{-1}) (ref. 14) iodinated with ¹²⁵I and were corrected for nonspecific binding.

during these experiments we found a pattern which differed from normal in that there was a double band in the region of glycoprotein I (Fig. 1). The first band corresponded in electrophoretic mobility to glycoprotein I while the mobility of the second band indicated a molecular weight 10,000–12,000 lower. Each of these components was present in about one-half the amount of glycoprotein I in normal platelets. Combining the values for peaks IA and IB gives ratios (IA+B:II:III:IV) of 63:23:7:7 and 63:18:9:10, respectively, for the two patients which are ratios similar to those found in normal controls.

Several different types of experiment were carried out to determine whether this polymorphism was an intrinsic property of the membrane glycoproteins in these two cases or could have arisen from extraneous causes. Since glycoprotein I is known to be particularly sensitive to proteolytic digestion^{1,3} the possibility of increased proteolytic activity in the patients' serum was investigated by incubating normal platelets with samples of plasma from the two subjects for 8 h at 37 °C; this did not result in the appearance of a double band in the membranes subsequently isolated from the treated platelets indicating that the double band did not result from extraneous proteolysis, nor was there any appearance of the second band on prolonged incubation of the platelets themselves indicating that it was not due to protease activity in the abnormal platelets. Peaks IA and IB were equally susceptible to added trypsin in intact platelets and a single PAS-positive band was observed in the soluble supernatant with an electrophoretic mobility indistinguishable from that of the macroglycopeptide obtained from normal platelets⁶. These observations suggested that differences in the electrophoretic mobility of peaks IA and IB probably were not due to structural differences in the macroglycopeptide portion of the two molecules.

Glycoprotein I seems to exist both in membrane-bound forms and in a form, glycocalicin, which is loosely bound within the platelet glycocalyx and is obtained in soluble form following platelet homogenisation¹. The relationship between glycoprotein I and glycocalicin is not clear, however, and they differ in their pattern of labelling with surface probes¹. Glycocalicin has been isolated and characterised⁷ and has been shown to be an inhibitor of

Table 1 Clinical laboratory studies

	Normal values	Subject 1 (female, aged 22 yr)	Subject 2 (female, aged 28 yr)
Platelet count (mm ⁻³)	150,000–450,000	400,000	290,000
Bleeding time (min)	4–10	6	5
Platelet retention (%)	> 35	23	10
Prothrombin time (s)	12–14	13.2	13.0
Activated PTT (s)	< 35	32	35
Aggregation (%)			
Collagen (2 µg)	> 65	35	75
Adrenaline (2.5 µM)	> 70	6	85
ADP (10 µM)	> 70	39	90
Ristocetin (1.5 mg ml ⁻¹)	> 80	100	88
Thrombin (0.2 units ml ⁻¹)	> 65	74	84
VIII _{VWF} (%)	55–120	86	81
VIII _{AHF} (%)	50–200	100	115
PF-3 (s)	60	72	ND

Platelets were counted by phase microscopy. Platelet adhesiveness was measured by a modified Salzman technique¹⁶, bleeding times by the template technique of Mielke¹⁷ and prothrombin times, activated partial thromboplastin times (PTT) and one stage Factor VIII bioassay by standard methods. VIII_{VWF} assays were performed by the quantitative technique of Weiss¹⁸, platelet factor 3 (PF 3) availability was performed by the kaolin technique¹⁹ and platelet aggregation by the turbidimetric method of Born²⁰. ND, Not determined.

thrombin-induced platelet aggregation⁸ and to have thrombin-binding activity associated with the (nonglyco) peptide 'tail' portion of the molecule (T.O. and G.A.J., submitted for publication). Although there was no resolution into two electrophoretic peaks, glyocalicin present in the soluble portion of the platelet homogenate in these two cases showed a broader distribution of electrophoretic mobilities as compared with controls and the amount present was in the low-normal range.

Quantitative studies of thrombin-binding were carried out by the filtration technique of Majerus⁹ in the high affinity range (0.020–0.080 units) considered to be significant for thrombin action under physiological conditions^{9–11}. Binding studies were carried out in cacodylate buffer which gives a 10-fold increase in binding efficiency¹². The number of thrombin-binding sites per platelet were calculated from double reciprocal plots according to Steck and Wallach¹³ using computer-assisted analysis to obtain best fit (Fig. 2). Data calculated in this way gave a value of 5,400 thrombin binding sites per platelet for normal controls but only one half that, 2,400 per platelet, for the two patients showing the glycoprotein abnormality. The reciprocal plots intersected at the abscissa indicating that there is no difference in the affinity for thrombin between the patients and controls: a value of 0.35 units ml⁻¹ was determined for half saturation of thrombin binding sites.

Although both the glycoprotein polymorphism and the decrease in thrombin binding were found consistently in these patients it was not possible to correlate these biochemical observations with clinical laboratory data (Table 1). In one case (subject 2) all values were within the normal range whereas in the other case (subject 1) there seemed to be an associated release defect. Associated release defects have also been noted in other cases of abnormal haemostasis¹⁵. It may be noted that thrombin-induced aggregation was normal in both patients. Binding of thrombin to platelets is kinetically complex^{9–11}, however, and it is not possible to predict a relationship between the number of thrombin receptors present and the extent of aggregation to be expected.

No evidence for a genetic basis for the polymorphism could be obtained within the limited family groups available: subject 1 gave no history of family bleeding problems while subject 2 gave a family history of easy bruising in her father, sister and daughter but without the more marked bleeding episodes of her late mother and herself. Examination of the three living family members failed to reveal any glycoprotein abnormality and all gave normal values for VIII_{AHF}, VIII_{VWF}, in routine coagulation and aggregation studies, and in thrombin binding.

Although it is not known whether this is the primary cause of the bleeding defects observed in these two individuals, the two cases described here show identical patterns of glycoprotein polymorphism and decreased thrombin binding capacity. Since the macroglycopeptide portions of the two components seem to be identical on the basis of electrophoretic mobility, and since the thrombin-binding site of glycoprotein I/glyocalicin is present in the peptide 'tail' (MW 45,000) of the molecule, these suggest that the lower molecular weight of the abnormal form of glycoprotein I may result from a deletion of structures associated with thrombin binding in that region. Direct correlation of the electrophoretic and functional data will require isolation and comparison of the two forms of glycoprotein I manifest in these individuals.

Interaction of colchicine with phosphatidylcholine membranes

EXPERIMENTAL results have suggested that the alkaloid drug colchicine affects the lateral mobility of membrane components^{1–5}. To explain these observations, Wunderlich *et al.*⁶ have proposed two alternative hypotheses: the lipophilic

drug intercalates into the lipid bilayer in a manner analogous to cholesterol; or colchicine acts by binding to membrane protein. It is well documented that in lipid bilayers of both model and biological membranes, the methylene groups of the lipid fatty acyl chains are more mobile near the chain terminus than near the glycerol backbone of the phospholipid, resulting in a gradient of increasing fluidity in the non-polar phase of the bilayer interior⁷⁻¹². From nuclear magnetic resonance (NMR) and spin-label electron spin resonance (ESR) studies it has been found that cholesterol, by intercalating between the phospholipid fatty acyl chain, markedly increases the rigidity of the hydrocarbon phase of the bilayer¹³⁻¹⁹. We present here the results of a detailed spin-label study using phosphatidylcholine (PC) liposomes to show that, in contrast with cholesterol, colchicine does not detectably change the rigidity of PC bilayers.

The spin labels used (see Fig. 1), 2,2,6,6-tetramethylpiperidine-1-oxyl (TEMPO), 2-(3-carboxypropyl)-4,4 dimethyl-2-tridecyl-3-oxazolidinyloxy (C_5 nitroxide-labelled stearic acid), 2-(10-carboxydecyl)-2-hexyl-4,4-dimethyl-3-oxazolidinyloxy (C_{12} nitroxide-labelled stearic acid) and 2-(14-carboxytetradecyl)-2-ethyl-4,4-dimethyl-3-oxazolidinyloxy (C_{16} nitroxide-labelled stearic acid) are convenient probes for the measurement of the effects of a perturbant on the hydrophobic phase of a lipid bilayer. An increase in the rigidity of the matrix of the fatty acyl chains is reflected by an increase in the hyperfine splitting ($2A'_{zz}$) in the ESR spectrum of the stearic acid spin labels and by a decrease in the parameter f of the TEMPO ESR spectrum²⁰ (see Fig. 1).

The results of replicate experiments indicate that on increasing the concentration of colchicine there was no change in the stearic acid spin label ESR spectra and no change in the f -value of TEMPO (ref. 20). As an example, ESR spectral parameters for 0 and 30 mg ml⁻¹ colchicine are listed in Table 1. However, an increase in cholesterol to phospholipid molar ratios over the range of the colchicine to phospholipid molar ratios (0.0-1.0) used in this experiment greatly increases the rigidity of the fatty acid acyl chains¹³⁻¹⁹.

From these results, there is no evidence to suggest that colchicine, like cholesterol, decreases the fluidity of the lipid

Fig. 1 ESR spectra from C_5 , C_{12} , C_{16} and TEMPO-labelled unsonicated lecithin dispersions containing 30 mg ml⁻¹ colchicine. For the C_5 and C_{16} spectra, $2A'_{zz}$ is defined by the horizontal distances indicated. From the TEMPO spectrum, the quantity f is defined as $h_L/(h_L + h_W)$, where h_L and h_W to a first approximation are proportional to the fraction of TEMPO in the lipid and water phases, respectively. H is the applied magnetic field.

Table 1 ESR data summary*

Label	Spectral parameter	
	Colchicine (0 mg ml ⁻¹)	Colchicine (30 mg ml ⁻¹)
TEMPO	$f = 0.38 \pm 0.01$	$f = 0.38 \pm 0.01$
C_5	$A'_{zz} = 26.0 \pm 0.2$ G	$A'_{zz} = 26.0 \pm 0.2$ G
C_{12}	Spectra superimposable; A'_{zz} is difficult to extract	
C_{16}	$A'_{zz} = 14.3 \pm 0.2$ G†	$A'_{zz} = 14.3 \pm 0.2$ G†

Phosphatidylcholine was extracted from egg yolks by the method of Singleton *et al.*²³ with the exception that the acetone, used for precipitation of the crude phosphatides, was used at dry ice temperature under N₂. This speeded precipitation and retarded atmospheric oxidation of the crude phosphatides, as determined by thin-layer chromatography. TEMPO was prepared by the method of Briere *et al.*²⁴. The nitroxide-labelled stearic acids were purchased from Syva. PC and the desired spin label in 1:200 molar ratio with PC were dissolved in N₂-saturated distilled chloroform and dried to a film using a rotary evaporator. The last traces of chloroform were removed under vacuum (about 6.0×10^{-5} atm) for 2 h. N₂-saturated buffer, 10 mM Tris, 5 mM KCl, pH 7.4, was added to the mixture to give a 100 mg ml⁻¹ PC dispersion. The slurry was agitated until no PC was seen adhering to the walls of the flask. Colchicine (Sigma), in buffer solution, was added to 0.5-ml aliquots of the PC dispersion to give a final PC concentration of 50 mg ml⁻¹ and colchicine concentrations ranging from 0 to 30 mg ml⁻¹. The PC-colchicine solutions were shaken on a vortex mixer for 1 min and allowed to equilibrate for at least 2 h at room temperature under N₂ before spectra were taken. The mixtures were vortexed again immediately before the taking of spectra. A parallel series of experiments was done with lipid dispersions sonicated as described by Godici and Landsberger for 25 min. Colchicine was added to these sonicated dispersions as described above. In one series of experiments, PC and colchicine in concentrations of 0 and 30 mg ml⁻¹ were co-sonicated in conditions previously described⁸. ESR spectra were obtained with Varian E-4 and E-12 spectrometers.

*Average values of replicate experiments using unsonicated dispersions.

† A'_{zz} is one-half the distance between the base-line crossings of the high and low magnetic field peaks of the ESR spectrum.

fatty acyl chains. The data also rule out any detergent-like interaction between colchicine and lipid membranes. Although the possibility is not rigorously precluded that colchicine inhibits lateral diffusion of lipids, as has been described for cholesterol^{21,22}, and hence that of membrane protein, this seems extremely unlikely. Colchicine, in concentrations similar to these cholesterol studies^{21,22} and up to 10⁴ times greater than those known to affect the lateral mobility of membrane components¹⁻⁵, does not affect the motional freedom of the lipid hydrocarbon chains.

Thus, we have tried to differentiate between the two hypotheses suggested by Wunderlich *et al.*⁶. We conclude that colchicine does not interact with the lipid bilayer in a manner analogous to that of cholesterol and that it seems that colchicine might interact with membrane and/or microtubular protein¹⁻⁶.

Are benzodiazepines GABA antagonists?

ALTHOUGH benzodiazepines are widely used in routine medical practice their mechanism of action remains controversial^{1,2}. Several authors have suggested that the action of benzodiazepines is to potentiate GABA-ergic processes in the central nervous system³⁻⁶. In addition, a number of studies have shown the effect of benzodiazepines to be antagonised by γ -aminobutyric acid (GABA) antagonists^{6,7}. But, Steiner and Felix⁸ and Gähwiler⁹ have adopted the opposite view and reported that in the cerebellum and Deiters nucleus benzodiazepines antagonise the inhibitory action of GABA. On the other hand, Dray and Straughan⁶ have shown microiontophoretic applications of benzodiazepines to be inhibitory on the spontaneous and glutamate activity of neurones of the brain stem and were unable to confirm that benzodiazepines antagonise the action of GABA. Curtis *et al.*¹⁰ were also unable to confirm the results of Steiner and Felix⁸ on the neurones of the cerebellum and spinal cord. In the recent paper by Squires and Braestrup¹¹ a direct interaction of benzodiazepines with GABA-receptors has been discarded. We have investigated the interaction between chlordiazepoxide (Librium) and GABA by observing the effects of simultaneous microiontophoretic application of both agents on the spontaneous and glutamate-evoked firing of single neurones of sensorimotor cortex of the rabbit and here we report that the actions of the two are synergistic.

The experiments were performed on seven adult rabbits anaesthetised with hexobarbitone sodium and artificially ventilated. Microiontophoresis and recording was from five to seven barrelled micropipettes of 4-6 μ m overall tip diameter. The central recording barrel was filled with 2M NaCl and only those neurones with extracellular action potentials of 1 mV or greater

Fig. 1 The dose-dependent action of microiontophoretically applied chlordiazepoxide hydrochloride (CDP) on the glutamate-evoked firing of a sensorimotor neurone. The iontophoretic application and the current passed in nA (1×10^{-9} A) are indicated by the horizontal bar and the figures above them. The rate meter was reset every 3 s. Retaining currents in all the experiments were between 15 and 45 nA.

Fig. 2 Synergism between chlordiazepoxide and GABA applied microiontophoretically to the same neurone. *a*, The failure of CDP to antagonise the inhibitory action of GABA. *b*, The summation of submaximal inhibition evoked by GABA and CDP. In (*a*) the activity of the neurone was maintained by the application of glutamate (3 nA) and the rate meter was reset every 3 s in (*a*) and 5 s in (*b*).

were studied. The concentration of chlordiazepoxide was 0.2M ($pH = 3.0$), and the other barrels contained sodium glutamate (1 M; $pH = 7.5$), GABA (1 M; $pH = 3.0$) and NaCl (3 M). GABA was applied with the minimum microiontophoretic ejecting current required to induce a marked and stable inhibitory effect of the agent on the spontaneous or glutamate-evoked activity of a given neurone. The effects of current flow on neuronal activity was minimised using standard current balancing techniques.

Figure 1 shows the marked reduction in activity evoked by a microiontophoretic application of chlordiazepoxide to a neurone of the sensorimotor cortex. This inhibitory action of chlordiazepoxide increased with the applied current and this effect was found on all 22 cells studied; in no trial did chlordiazepoxide increase neuronal activity.

Figure 2a shows the failure of chlordiazepoxide to antagonise the action of GABA. Similar results were obtained on 14 neurones and no antagonism between chlordiazepoxide and GABA was observed during the application of chlordiazepoxide with currents between 2 and 120 nA. Similar results were obtained in two additional experiments in which anaesthesia was induced and maintained with urethane or chloralose.

In complete contradiction to the suggestion that chlordiazepoxide antagonises the action of GABA we have found the inhibitory action of chlordiazepoxide to be synergistic with that of GABA. In Fig. 2b, for instance, small applications of both GABA and chlordiazepoxide which evoked only small degrees of inhibition combine to induce almost complete inhibition. Since in previous studies we observed systematically administered diazepam to potentiate the action of GABA on the spontaneous

activity of neurones in the sensorimotor cortex¹², we suggest that the actions of benzodiazepines and GABA are synergistic.

Agonist-antagonist properties of *N*-allyl-[D-Ala]²-Met-enkephalin

RECEPTOR displacement of the opiate antagonist naloxone requires concentrations of morphine and other opiate alkaloids similar to those required to elicit analgesia^{1–3} or inhibit ileal contraction^{4–5}. A new class of opiates with structures based on the discovery of endogenous, morphine-like pentapeptide—enkephalin⁶—also displace opiate receptor binding with potencies paralleling *in vivo* activities^{7–10}. Intrinsic activity (agonist or antagonist quality), a different dimension of opiate alkaloid effects *in vivo*, is closely correlated with the *in vitro* effects of sodium ion in the incubation medium: while antagonist binding to opiate receptors labelled by radioactive naloxone is almost unaffected by sodium ion addition, opiate alkaloid agonists become 10–60-fold weaker and mixed agonist-antagonists have intermediate downward shifts in apparent affinity after sodium ion addition^{1–11}. We present here an analysis of the sodium sensitivities of the major opiate peptides which have all been identified as 'agonists' thus far. In addition, we describe the synthesis, behavioural and *in vitro* receptor analysis of *N*-allyl-[D-Ala]²-Met-enkephalin (Fig. 1), a novel peptide whose structure was designed in analogy¹² with that of the alkaloid opiate antagonists¹³ in order to obtain a peptide opiate antagonist, if possible.

The sodium ion dependence of the receptor interactions of morphine, *N*-allyl-[D-Ala]²-Met-enkephalin and three opiate peptides is shown in Fig. 2. Like the prototype opiate agonist morphine, [D-Ala]²-Met-enkephalinamide (an enzyme-resistant enkephalin)¹⁴ and the C fragment of β -lipotropin (61–91) (refs 15–17) show large 'sodium shifts' of 25 and 17 respectively. This is consistent with recent reports which indicate that these peptides are morphine-like agonists as analgesics^{9,14,18,19}, and in the guinea pig ileum^{10,16}. It should be noted that Bradbury *et al.*¹⁵ reported a 'sodium shift' for the C-fragment of only 1.3. In

Fig. 1 Structure of *N*-allyl-[D-Ala]²-Met-enkephalin. *N*-allyl-L-tyrosine (A) was synthesised from *N,O*-dibenzoyl-L-tyrosine methylester by reaction with sodium hydride and allyl bromide and purified by countercurrent distribution. Reaction of A with *tert*-butoxycarbonyl azide gave the *N*-protected derivative (B). D-Alanyl-glycyl-L-phenylalanyl-L-methionine (C) was prepared by stepwise condensation using *N*-hydroxysuccinimide esters. The crystalline tetra-peptide gave the expected amino acid analysis. B was converted to the *N*-hydroxysuccinimide ester and coupled to C. Following deprotection the homogeneity of *N*-allyl-[D-Ala]²-Met-enkephalin was ascertained by countercurrent distribution, the product showing this amino acid analysis (residues per mol): glycine, 1.00; alanine, 0.94; methionine, 1.00; *N*-allyl-tyrosine, 0.85 (C-value 0.09 of that of leucine; *N*-allyltyrosyl peptides are resistant to hydrolysis and A is subject to destruction); phenylalanine, 1.00.

the same study, the sodium sensitivity ratio of morphine was only 7 in contrast to the larger values of 38 obtained in these experiments and values of 33–40 consistently obtained in previous studies^{1,11,20}. The methodological difference which probably accounts for the discrepant values¹⁵ is the lack of incubation at 0 °C, since low temperature is essential for demonstrating sodium effects reproducibly²⁰.

The sodium shift value of Met-enkephalin⁹ suggests a predominantly agonist nature, but falls within the range of opiates which display partial antagonist activity in some test situations¹¹. A recent study²¹, indeed, suggests that Leu-enkephalin despite its three to fourfold reduced affinity for brain opiate receptors^{7,8}, maintains intraventricular self-administration behaviour more readily than Met-enkephalin because it is a 'purer' agonist. No antagonist activity is detectable for Met-enkephalin in the guinea pig ileum²², however.

In striking contrast to morphine and the opiate peptide agonists, *N*-allyl-[D-Ala]²-Met-enkephalin has a small (2.5) sodium response ratio which clearly suggests antagonist properties if sodium effects on peptides are as relevant to *in vivo* pharmacological activity as they are for opiate alkaloids. Intraventricular injection of the putative peptide antagonist, *N*-allyl-[D-Ala]²-Met-enkephalin, however, does not decrease the anti-nociceptive response obtained when [D-Ala]²-Met-enkephalin is injected alone (Table 1). In fact, the allyl peptide injected alone is a weak analgesic, suggesting the presence of weak agonist activity compatible with its rather low affinity for opiate receptors. The 'narcotic antagonists' (nalorphine, levallorphan and so on) also elicit analgesia in the tail-flick test and produce sodium ratios in the 1.5–3.0 range¹¹.

The various pharmacological assays for opiates are known to differentially emphasise their agonist or antagonist qualities. For example, chronic morphine administration causes a dramatic 'supersensitivity' to opiate antagonist activity so that much lower doses of antagonists are required to precipitate opiate withdrawal signs²⁴. We therefore examined the ability of *N*-allyl-[D-Ala]²-Met-enkephalin to produce withdrawal signs in

Table 1 Behavioural effects of *N*-allyl-[D-Ala]²-Met-enkephalin

Analgesic effects		Tail-flick latency
Drug		(s ± s.e.m.)
Vehicle		3.9 ± 0.16 (n = 7)
<i>N</i> -Allyl-[D-Ala] ²		7.4 ± 1.49 (n = 6)*
[D-Ala] ²		10.4 ± 1.23 (n = 7)*
[D-Ala] ² + <i>N</i> -allyl-[D-Ala] ²		13.5 ± 0.65 (n = 7)**
Withdrawal	Vehicle (n = 4)	<i>N</i> -Allyl-[D-Ala] ² (n = 7)
Wet-dog shakes	0.75 ± 0.75	3.86 ± 2.0
Chewing	0	1.71 ± 0.36

To test analgesic effects 27 rats were implanted with 22 ga cannulae guides, the tips of which were aimed for an area 2 mm above the third ventricle (AP 3.0, LAT 0.0, DV 2.5)²³. Two weeks after the operation the animals were divided into four groups and injected in the third ventricle with either 7 μ l water (vehicle), 35 μ g *N*-allyl-[D-Ala]² in 7 μ l water, 20 μ g D-Ala in 4 μ l water or 20 μ g D-Ala followed immediately by 35 μ g *N*-allyl-[D-Ala]². Analgesic effects were assessed 15 min after injection with the tail-flick task as previously described¹⁴ with the exception that the tail-flick response limit was increased to 15 s. In withdrawal tests 10 rats were implanted with intracerebral cannulae guides as above. One week later all animals were implanted subcutaneously with one 75 μ g morphine pellet. Forty-eight hours later they were implanted with two additional pellets and 48 h after the second pellet implantation the animals were divided into two groups and injected with either 35 μ g *N*-allyl-[D-Ala]² or 7 μ l water. Total number of wet-dog shakes and jumps were recorded for 30 min after injection. Ptosis, chewing, teeth chattering, eye twitching, or squeal on touch²⁵ were rated at 10-min intervals during the same observation period. Only wet-dog shakes and chewing were found to increase following *N*-allyl-[D-Ala]².

**P* < 0.05 for comparison of drug effects with vehicle control.

†*P* < 0.05 for comparison of D-Ala + *N*-allyl-[D-Ala]² with D-Ala alone.

Fig. 2 Sodium sensitivity of the displacement of stereospecific ^3H -naloxone binding by several opiate peptides and morphine. Male Sprague-Dawley rats were killed by guillotine, their brain minus the cerebellum was rapidly removed and placed in 100 volumes of cold (4°C) 0.05 M Tris buffer (Trizma Preset pH crystals, pH 7.4 at 0°C) and homogenised with a Polytron set at number five for 15 s. The crude homogenate was centrifuged at $12,000g$ for 15 min, the supernatant discarded and the pellet reconstituted in 100 volumes of buffer. After repeating centrifugation and decanting, the pellet was resuspended in 10 ml of cold buffer by vortexing for 10 s and brief Polytron treatment. Membranes were prepared for use no later than 1 h after the final resuspension. The assay was incubated in duplicate in an ice water bath for 60 min in $10 \times 75\text{-mm}$ glass test tubes containing brain membranes (100 μl), peptides (abscissa), 50 μl ^3H -naloxone (2.4 nM, 20,000 c.p.m., 19.9 Ci mmol^{-1}), and 50 μl of 1 M sodium chloride (closed symbols) or buffer (open symbols), and sufficient Tris buffer required for a final volume of 500 μl . Membranes were added last. After 60 min each reaction mixture was briefly vortexed, then filtered under reduced pressure through Whatman GF/B filters and washed twice with 7 ml of ice-cold buffer in a filtration cycle of less than 10 s. Filters were transferred to vials and, after the addition of scintillation fluid (AquaSol, NEN) were counted in a Beckman LS-230 Scintillation counter at 45% efficiency. Control values of stereospecific ^3H -naloxone binding were calculated by subtracting nonspecific binding (c.p.m.) which occurred in the presence of 100 nM levallorphan. Control values from five experimental runs for total receptor binding and levallorphan binding were $1,625 \pm 72$ c.p.m. and 726 ± 172 c.p.m. respectively in the absence of sodium and $2,472 \pm 280$ c.p.m. and 429 ± 72 c.p.m. in the presence of sodium. ID_{50} and sodium ratio values, which varied less than 2-fold, were determined as the means from two experimental runs. All inhibition values between 15% and 85% for one experimental run are shown. In a: \bullet , \circ , [D-Ala]²-enkephalin; \square , \blacksquare , N-allyl-Tyr-[D-Ala]²-enkephalin. In b: \bullet , \circ , morphine; \blacktriangle , \triangle , C fragment (LPM 61-91); \blacksquare , \square , Met-enkephalin.

rats made dependent on morphine²⁵ in an attempt to demonstrate antagonist properties. Intraventricularly-injected morphine pellet-implanted rats indeed developed weak opiate withdrawal signs of 'wet-dog shakes' and chewing behaviour which were not present in the vehicle-injected controls (Table 1).

While further characterisation of the pharmacology of additional opiate peptides is required before a definite conclusion can be reached, these experiments show that the *in vitro* sodium effect provides information about the agonist-antagonist quality of opiate peptides when assessed in the very specific experimental conditions described here. The sodium effect probably occurs because receptors for endogenous as well as exogenous opiates exist as an inter-converting equilibrium between an agonist conformation and an antagonist conformation associated with a sodium binding site^{11,26,27}.

N-Allyl-[D-Ala]²-Met-enkephalin seems to be a weak agonist with mild antagonist character *in vivo* with a small sodium shift *in vitro* like that of opiate alkaloid partial antagonists. The clinically undesirable effects of chronic opiate administration have previously been demonstrated for [D-Ala]²-Met-enkephalinamide⁹, β -LPH (61-91) (ref. 28), and Met-enkephalin²⁶. Opiate peptides with partial antagonist quality might have diminished physical dependence and tolerance liability like the analgesics in the mixed agonist-antagonist benzomorphans group of opiates²⁹. In any case, these results suggest the feasibility of developing a 'pure' opiate peptide antagonist by *in vitro* analysis. Such an antagonist might more readily block the physiological actions of endogenous opiate peptide ligands; Lord *et al.* have already shown that the currently available alkaloid antagonists are surprisingly weak at blocking some actions of opiate peptide agonists³⁰.

We thank Dr Derek Smyth for the gift of the C fragment

of β -LPH used in these studies. Met-enkephalin and [D-Ala]²-Met-enkephalin were obtained from Dr Jaw-Ken Chang.

Note added in proof: Hahn *et al.*³¹ have found that N-allyl-Leu-enkephalin has antagonist properties in the guinea pig ileum.

Subcellular localisation of leucine-enkephalin-hydrolysing activity in rat brain

THE naturally-occurring pentapeptides leucine- and methionine-enkephalin which exhibit agonist activity at the opiate receptor¹ are subject to rapid deactivation by tissue homogenates^{2,3}. The primary mode of degradation has been demonstrated to be cleavage of the Tyr-Gly amide bond^{4,5}. It is not surprising, therefore, that the opiate actions of the exogenously administered peptides are transient^{6–9} and the biological half life of the peptides is very short. We have previously studied degradation of the enkephalins in relatively crude preparations and we present here a study of the subcellular localisation of enkephalin-hydrolysing activity (EHA) in rat brain. We found a heterogeneous distribution of EHA in rat brain subfractions and evidence for enzyme heterogeneity. Opiate receptors are apparently functionally unrelated to the site of EHA in synaptic membranes.

Rat brain subcellular fractions were obtained from whole rat brain, excluding medulla and cerebellum, by the method of Whittaker¹⁰. Blood was obtained by cardiac puncture and

Table 1 Enkephalin-hydrolysing activity in rat plasma, CSF and unlysed brain subfractions

Tissue (fraction†)	Enzyme specific activity*	Total protein (mg)
Plasma	2.41 ± 0.31 (6)	39.2 ± 7.45 ml ⁻¹
CSF	2.00 ± 0.85 (10)	0.54 ± 0.26 ml ⁻¹
Brain soluble (S ₃)	30.54 ± 5.57 (5)	36.05 ± 5.41
Nuclear (P ₁)	7.51 ± 1.22 (5)	11.82 ± 1.57
Microsomal (P ₃)	3.29 ± 1.11 (5)	24.38 ± 5.63
Myelin (A)	0.96 ± 0.91 (5)	10.63 ± 3.07
Synaptosomal (B)	7.75 ± 1.47 (5)	15.80 ± 2.40
Mitochondrial (C)	4.84 ± 1.76 (5)	21.19 ± 5.71

Values are mean ± s.d.; number of determinations in parentheses. The assay mixture, containing [3,5-³H]-Tyr]-Leu⁵-enkephalin (1 μCi, final concentration 10⁻⁴ M), 0.5 M Tris-HCl buffer pH 7.4 (0.1 ml), and the preparation to be assayed (50–200 μg, protein), was diluted with distilled water to a final volume of 0.5 ml. The mixture was incubated at 37 °C for 15 min and an aliquot (0.2 ml) taken and added to ice cold methanol (0.1 ml). After separation of the denatured proteins by centrifugation, an aliquot (0.05 ml) of the supernatant was applied in a narrow band to the foot of a silica gel thin-layer plate (Kieselgel-GF₂₅₄, 5 × 20 cm, Merck) together with authentic samples of tyrosine and Leu⁵-enkephalin. After development using chloroform-methanol-acetic acid-water (45:30:6:9, v/v) as solvent, the markers were visualised with ninhydrin (1%, w/v in acetone). Zones corresponding to the substrate and product were scraped and the silica suspended in a mixture of water (2 ml) and PCS (5 ml, Amersham-Searle). Radioactivity was determined using a Packard 2450 scintillation counter. Protein concentrations were determined by the method of Lowry *et al.*¹¹.

*Enzyme specific activity expressed as nmol enkephalin hydrolysed per mg protein per min.

†Letters in parentheses refer to the classification of subcellular fractions as used by Whittaker¹⁰.

cerebrospinal fluid (CSF) by puncture of the cisternum magnum of rats. The EHA was assayed using [3,5-³H]-Tyr]-Leu⁵-enkephalin (Radiochemical Centre, Amersham) as substrate, by either determining the rate of formation of [3,5-³H]-tyrosine or the rate of disappearance of the substrate after thin-layer chromatographic separation of the two tritiated species.

The pH optimum for EHA in plasma, synaptosomes and brain high speed supernatant was pH 7.2. Significant EHA was found in all subcellular fractions (Table 1). Plasma, in contrast to CSF, was found to be a potent source of EHA. This is consistent with the results of studies reporting detection of enkephalin-like activity in CSF (refs 12, 13). The soluble fraction (S₃) of rat brain was also a good source of EHA. Of the particulate fractions examined synaptosomal (B) and nuclear (P₁) fractions showed highest enzyme specific activity. The even distribution of EHA in a crude membrane fraction (P₂) from various rat brain regions shown by Meek *et al.*⁵ would be expected from the considerable EHA associated with the mitochondrial fraction as this activity would contribute to a high background level of EHA of other than synaptosomal origin.

In view of the putative role of the enkephalins as inhibitory neurotransmitters or neuromodulators, it was of particular interest to explore the localisation of the synaptosomal enzyme. The synaptosomal fraction (B) was lysed by suspension in water for 30 min at 0–1 °C. The lysate was then fractionated on a discontinuous sucrose gradient as described by Whittaker¹⁰. The activity of the subfractions obtained is shown in Table 2. Some soluble enzyme was released which possessed similar activity to that obtained in the soluble fraction from whole brain. The synaptosomal

Table 2 Enkephalin-hydrolysing activity in rat brain lysed synaptosomal subfractions

Fraction (fraction†)	Enzyme specific activity*	Total protein (mg)
Soluble (O)	35.26 ± 12.0 (4)	2.49 ± 1.33
Vesicular (D, E)	0.91 ± 1.00 (4)	1.30 ± 0.56
Synaptosomal membranes (F, G, H)	2.62 ± 0.96 (4)	7.40 ± 4.93

†Letters in parentheses refer to classification of Whittaker¹⁰.

mitochondrial fraction also possessed activity similar to that found in the mitochondrial fraction from whole brain. The EHA associated with the vesicular fraction was low whereas significant EHA was associated with the synaptosomal membrane fractions (F, G, H) and this latter activity may have a significant role in terminating the physiological action of the enkephalins.

Simantov *et al.*¹⁴ have shown that synaptosomes contain the highest levels of enkephalin activity and this study shows that substantial EHA is present in intact synaptosomes, so it follows that enkephalins must be protected from hydrolysis in some way, possibly by sequestration within vesicles. This would be consistent with the evidence presented here and analogous to the subcellular storage and inactivation of acetylcholine¹⁰.

It was of interest to examine the sensitivity of EHA in brain subcellular fractions to various reagents in an attempt to cast some light on the uniformity of enzyme activity present. The results are presented in Table 3. Rat brain EHA was uniformly inhibited by leucyl-β-naphthyl-

Table 3 Effect of various reagents on rat brain and plasma enkephalin-hydrolysing activity

Tissue (fraction)	Leucyl- β -naphthylamide	EDTA*	p-Chloromercuribenzoate
Plasma	41	14	0

amide (0.5 mM). The patterns of inhibition observed with EDTA and p-chloromercuribenzoate did not run in parallel suggesting considerable enzyme heterogeneity in the fractions studied.

In view of the structural similarities demonstrated^{15,16} between the enkephalins and standard opiates it seemed possible that the latter could be competitive inhibitors of EHA. Of a series of compounds tested (buprenorphine, etorphine, fentanyl, ketocyclazocine, methadone, morphine, nalorphine, naloxone, pentazocine and pethidine) representing a wide range of structures and activities, only etorphine, fentanyl and methadone showed any inhibitory properties (about 50% at 0.66 mM, the highest concentration tested). In the light of the high affinity that the majority of these compounds demonstrate for the opiate receptor, it can be concluded that the pharmacological receptors and the sites of enzyme activity in synaptic membranes are functionally unrelated.

In summary, a heterogeneous distribution of EHA has been observed in rat brain subfractions. The demonstration of activity in the synaptic membrane fraction and the low level of activity found in the synaptic vesicle fraction are observations not inconsistent with the putative role of the enkephalins as neurotransmitters or neuromodulators.

Unconventional serotonergic excitation in *Aplysia*

EXCITATORY potentials of long duration have been observed in vertebrate¹⁻³ and invertebrate^{4,5} neurones. In *Aplysia*, Gerschenfeld and Paupardin-Tritsch⁴ have found that 5-hydroxytryptamine (5-HT) can produce two kinds of long excitatory responses (A' and α) with different ionic mechanisms. The A' response was described as an increase in sodium conductance. The response became smaller as the cell was depolarised, and was extrapolated to a reversal potential of 0 mV. In contrast, the α response was attributed to a decrease in potassium conductance, since it had a reversal potential near -80 mV and became larger as the cell was depolarised. Krnjevic *et al.*³ and Weight and Votava¹ have hypothesised a similar mechanism for the long excitatory potentials which they observed in cat cortical neurones and frog sympathetic ganglia, respectively. Using the voltage clamp technique we observed a prolonged excitatory response to 5-HT, the characteristics of which are unlike either of those described previously. At hyperpolarised levels it resembles the A' response, becoming smaller with depolarisation, but at depolarised potentials the amplitude of the response dramatically increases.

Long excitatory responses with this characteristic could be recorded in cells of the left caudal quarter of the abdominal ganglion and in unidentified neurones of the buccal ganglia of *Aplysia californica*. The ganglion was pinned out and bathed in a solution of artificial seawater at pH 7.8. Cells were impaled with a glass capillary microelectrode filled with 1.5 M KCl. Membrane potential was clamped by the single microelectrode method of Wilson and Goldner⁶. An iontophoretic electrode containing a saturated solution of 5-HT was positioned extracellularly, and adequate bias current was applied to prevent leakage of the transmitter. To eject the 5-HT, standard pulses of positive current were passed through the electrode at a constant frequency of about once every 5 min. At this rate, desensitisation would not occur. It was ensured that the amplitude of the response was constant and that manipulation of membrane potential and the perfusion of seawater solutions would not alter the response. Since membrane potential was held constant by the voltage clamp, a depolarising response is expressed as inward current.

The membrane potential dependence of the long excitatory response is illustrated in Fig. 1a and b. As the cell is depolarised from -80 to -30 mV, the current response decreased in amplitude. Above -30 mV, the current response dramatically increased in size. In other cells this dramatic increase occurred at potentials as negative as -40 mV. Additionally, at depolarised levels, the current was prolonged and reached a maximum amplitude more slowly. The response seems to be comprised of two components: a linear component (1 in Fig. 1b) at hyperpolarised levels and a nonlinear component (2 in Fig. 1b) which begins to influence the response between -40 and -50 mV. This nonlinear component was observed in over 80% of the cells in which a prolonged excitatory serotonergic response was recorded (25 cells). In each case where component 2 was seen, it was as distinct and prominent as the sample shown in Fig. 1b.

Occasionally, the long response to 5-HT was accompanied by an excitatory response with a short time course (the A response of Gerschenfeld and Paupardin-Tritsch⁴). This fast response behaved in a totally conventional manner. As reported by Gerschenfeld and Paupardin-Tritsch⁴, the response became smaller with depolarisation and seemed to have a reversal potential near 0 mV. At potentials where the prolonged response was enlarged, the fast response in the same cell was extremely reduced in amplitude. This was

Fig. 1 *a*, Prolonged excitatory response to 5-HT. Cell membrane potential was voltage clamped and current was recorded. Ionophoretic pulse was applied at the dot. At -10 mV the response is prolonged and greatly enhanced. Calibration: 2 nA, 24 s. *b*, Plot of membrane potential against response amplitude for the same cell as in *a*. The response seems to be composed of two components: a linear component, labelled 1 and a non-linear component, labelled 2. *c*, Current-voltage relationship for the same cell as in *a* and *b*. Note the correspondence between the increase in the conductance of the cell and the enhanced response to 5-HT.

taken as evidence that the enhanced component 2 of the long response was not simply an artefact of the voltage-clamping system, for if it were, the short response would be equally enhanced.

A comparison of the current-voltage relationship of the cell (Fig. 1*c*) and the amplitude-potential relationship of the response to 5-HT (Fig. 1*b*) shows that the 5-HT response increased dramatically at the same potential where the membrane conductance increased. In the illustrated

cell this point was approximately -20 mV (compare Fig. 1*b* and *c*). We considered the possibility that the anomalous response to 5-HT at depolarised levels (component 2) could be due to a reduction in the potentiated membrane conductance at these potentials. Figure 2 shows the results of conductance measurements before and during a response to 5-HT. While the potential of the cell was clamped to -12 mV, hyperpolarising command pulses were applied to the cell every 20 s. During the response to 5-HT the current change produced by these pulses was reduced, indicating an apparent conductance decrease. At membrane potentials more negative than -30 mV, this reduction in membrane conductance was not observed. In fact, there was either a small increase in conductance or, often, no measurable change at all in the membrane conductance of the cell during the response at -80 mV.

The apparent decrease in membrane conductance, at potentials above -30 mV could be due to a decrease in potassium or chloride conductance. Preliminary ion substitution experiments show that this is not the case. In both high (30 mM) and low (1 mM) extracellular potassium, the response was unaffected. Decreasing extracellular chloride concentration to 77 mM was also without effect on the excitatory response to 5-HT. Figure 3*a* shows a typical ion substitution experiment. This particular experiment illustrates that elevation of extracellular potassium does not alter the response.

The apparent decrease in conductance could also be due to a voltage-sensitive increase in inward sodium current. In Fig. 1*b*, the line labelled 2 can represent such a current. As the cell is depolarised, the inward current is enhanced. Summing this component of the response with the current produced by a voltage-independent conductance change (1 in Fig. 1*b*) would result in the observed response. Since component 2 would be reduced during a hyperpolarising command, there would be an apparent conductance decrease. Such a voltage-sensitive sodium or calcium conductance has been shown to underlie the regenerative slow wave potentials and negative resistance region of bursting cells⁷. This possibility is supported by ion substitution experiments. Replacement of extracellular sodium with sucrose consistently attenuated both components of the response, suggesting that the response is in some way dependent on sodium ions (Fig. 3*b*).

It is likely that the unconventional response shown here is actually the A' response of Gerschenfeld and Paupardin-Tritsch⁴, which was attributed to an increase in sodium conductance. Since their observations were made in an unclamped cell, rectification prohibited their recording at

Fig. 2 *a*, Long excitatory response to 5-HT, administered at the dot. Membrane potential was voltage clamped to -12 mV. *b*, Hyperpolarising voltage commands applied before and during an identical response to 5-HT. The current change produced by the voltage commands is reduced during the response. Calibration: 2 nA, 48 s.

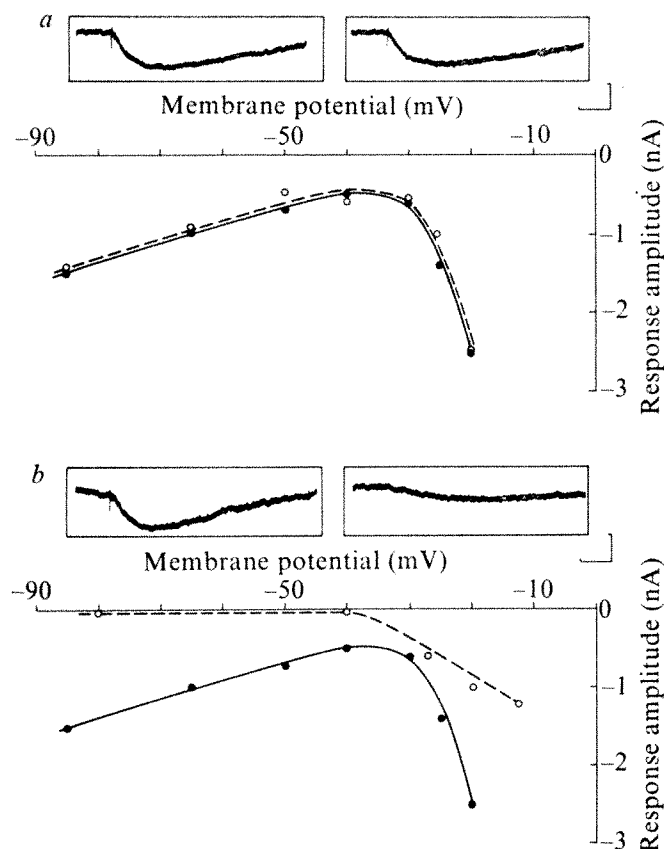

Fig. 3 Effect of ion substitutions on the long excitatory response to 5-HT. The responses shown in *a* and *b* were obtained from the same cell. *a*, Sample responses in normal (left) and 30 mM K^+ seawater (right) were recorded while the cell was voltage clamped to -20 mV. Calibration: 2 nA, 24 s. A plot of membrane potential against response amplitude illustrates that high potassium seawater (\circ) does not alter the responses obtained in normal seawater (\bullet). *b*, Sample responses at a membrane potential of -20 mV were greatly attenuated by Na^+ -free seawater, in which sucrose was added to maintain isotonicity. Calibration: 2 nA, 24 s. A plot of membrane potential against response amplitude illustrates that the Na^+ -free seawater (\circ) reduced the response at all membrane potentials. \bullet , Normal seawater.

very depolarised levels⁴. Fig. 1*b* shows that component 2 of the response would be missed unless potentials above -30 mV were sampled. Extrapolation of the curve consisting of only the points below -30 mV would indicate a reversal potential near -20 mV which is similar to that of conventional, sodium-dependent response^{4,6}. It is unlikely that the response we have observed is due to the stimulation of a combination of receptors which produce an increase in sodium conductance and a decrease in potassium conductance (A' and α , respectively). Our second component can first be seen to influence the current response near -40 mV and seems to have no effect on the response at more hyperpolarised potentials. Also the response is insensitive to changes in extracellular potassium concentration.

Our data show an unconventional long excitatory response to 5-HT. The response at hyperpolarised potentials behaves simply as an increase in sodium conductance, whereas at depolarised potentials the current is enhanced and accompanied by an apparent decrease in membrane conductance. This unusual component may be due to serotonergic activation of a voltage-sensitive sodium conductance, whereas conventional synaptic and iontophoretic responses result from voltage-independent conductance changes. The response we described represents a new type of neurotransmitter action: the induction of voltage-sensitive ionic channels.

Light-induced fluctuations in membrane current of single toad rod outer segments

VERTEBRATE photoreceptors respond to illumination with a reduction in the steady current of Na ions which in darkness flows inwards across the outer segment membrane; this results in hyperpolarisation of the cells¹. The light responses of the receptors can be studied by measuring extracellular voltage gradients² or by intracellular recording³, but these methods can only provide information averaged over many photoreceptors owing respectively to high extracellular conductivity and to the presence of electrical coupling between cells^{3–6}. This averaging and the presence of dark voltage noise in photoreceptors^{6,7} have prevented observation of the electrical effects of individual photoisomerisations. To try to record these elementary events and to localise the source of the dark noise, we have developed a method for recording the membrane current of a single rod outer segment. The technique is based on that used by Neher and Sakmann⁸ on muscle fibres.

Small pieces of retina were isolated from dark-adapted toads, *Bufo marinus*, and maintained in previously oxygenated toad Ringer⁹. On the stage of an inverted microscope fitted with an infrared image converter, a single rod outer segment was drawn under visual control into a close-fitting suction electrode containing Ringer (Fig. 1). The resistance of the suction pipette was initially 1–2 M Ω and rose to 4–10 M Ω with an outer segment in place. A current sensor between the pipette and a reference electrode in the bathing solution recorded the bulk of the membrane current flowing across the region of outer segment within the pipette. Recording resolution was limited by thermal noise in the leakage resistance of the space between the electrode wall and the outer segment, and to measure transient currents of the order of picoamps the bandwidth was normally restricted to 5–10 Hz.

Flashes of light evoked net outward photocurrents which were graded with stimulus intensity. As in previous extracellular² and intracellular^{3–5,9,10} measurements, the response amplitude saturated with increasing intensity in a hyperbolic manner. The half-saturating photon density was about 1 photon μm^{-2} for 'red' rods stimulated with 500 nm light, comparable with results obtained with intracellular voltage recording⁴, and the maximum photocurrent obtainable from a cell corresponded closely to complete suppression of its dark current, with values for different cells ranging up to 23 pA. Although intracellular voltage responses to bright

Fig. 1 Arrangement for recording membrane current of a rod outer segment. A suitably oriented outer segment was drawn by gentle suction into a close-fitting glass electrode, E, with fire-polished and vinyl-coated tip (Stoner-Mudge resin, Mobil). Membrane current, i_m , was recorded with amplifier A, a Function Modules model 380K, selected for low noise⁸. V, variable voltage used to compensate differences in electrode potentials and to measure electrode resistance. Amplifier output, $-i_m R$, was further amplified and recorded on a chart recorder and an FM tape recorder. Feedback resistance, R, 100 M Ω .

flashes display a prominent initial transient component^{4,9}, no such phase has been seen in the membrane current response from the outer segment. This may indicate that the voltage-sensitive channels generating the transient are not located in the outer segment. The dim flash responses were often considerably slower than the corresponding responses observed previously with internal electrodes⁴, with times to peak of 2–6 s. The reason for this is not clear, but it might result from our procedure of cutting the retina into small pieces.

Responses of a rod to a series of dim flashes of fixed intensity applied locally on its outer segment are shown in Fig. 2. There was considerable variation in response amplitude and four flashes seem to have failed to elicit a response. Measurement of the peak amplitude gave a mean of 2.0 pA and a variance of 2.2 pA², which, assuming a Poisson distribution, indicates an event size of 1.1 pA and

Fig. 2 Responses of a 'red' rod outer segment to brief flashes of blue-green light delivered at intervals of 12 s. Membrane current above, outward current upward, bandwidth 5 Hz; stimulus monitor below. Stimuli were local slits of light slightly larger than the 40 μm length of outer segment in the electrode. Intensity of the 500 nm stimulus at the preparation was estimated from readings of the unattenuated light made with a Tektronix digital irradiance meter and from *in situ* calibrations of the neutral density filters made with a photon counter (Princeton Applied Research, Quantum photometer). The flash width at half amplitude was 18 ms, and the estimated mean photon density was 7.9×10^{-2} photons per μm^2 per flash. The effective collecting area of the portion of the outer segment in the electrode was estimated as 12.5 μm^2 from measurements of cell dimensions, assuming an axial pigment density of 0.016 μm^{-1} and a quantum efficiency of isomerisation of 0.65.

a mean of 1.8 events per response. If a correction were made for nonlinear summation, the estimated event size would increase somewhat, and the mean number of events per flash would correspondingly decrease. The intensity of the light applied to the preparation was determined from photometer and photomultiplier readings as 0.079 photons μm^{-2} which was estimated to cause a mean of 0.99 photoisomerisations in the portion of outer segment within the suction pipette. This number of events is in reasonable agreement with the value of 1.8 estimated from the current fluctuations.

Figure 3 illustrates responses of the same rod to steady lights of increasing intensity. The lowest intensity (a) gave a response which rose with a considerable delay after the shutter opened and which fluctuated and then disappeared

Fig. 3 Responses of the outer segment of Fig. 2 to steady lights of increasing intensity. Upper traces (a–d): membrane current, bandwidth 10 Hz; lower trace: stimulus monitor. For each response the intensity of 500 nm light was (photons $\mu\text{m}^{-2} \text{s}^{-1}$): a, 6.1×10^{-3} ; b, 2.0×10^{-2} ; c, 3.6×10^{-2} ; d, 30.

before the shutter closed. Two higher intensities (b, c) gave larger responses still marked by fluctuations, but a saturating light (d) gave a smooth response. The light for trace (a) had an intensity of 0.0061 photons $\mu\text{m}^{-2} \text{s}^{-1}$, which should on average have caused about 0.076 photoisomerisations per second in the recorded region of outer segment. On this basis the number of isomerisations expected in a 60-s stimulus would have been 4.6 ± 2.1 . Inspection of trace (a) shows four discrete deflections although it is possible that more events may have occurred. The absence of a response in the later part of the trace presumably resulted from the absence of any isomerisations during that period. In trace (b) the mean response during illumination was 2.5 pA and the variance was 0.7 pA². Ignoring nonlinear summation of elementary events and taking a shape factor¹¹ of 0.68 gives the amplitude of the elementary event as 0.42 pA, in rough agreement with that obtained from the flash run. The mean number of simultaneous events in trace (b) would then have been 6.0, which, with an integration time³ of 8 s (from the flash responses of Fig. 2), corresponds to 0.75 events per second, as compared with a rate of 0.25 photoisomerisations per second estimated from the light intensity and cellular dimensions.

Assuming that the driving potential on the light-

sensitive conductance is 40 mV (refs 1, 3, 10), the observed current event of about 1 pA would correspond to a photon-induced conductance decrease of 25 pS. This is comparable to the conductance of an acetylcholine channel^{11,12}, but several times larger than that of a sodium channel in nerve^{13,14}. An elementary current event of 1 pA together with the measured flash sensitivity of 700 μ V per photoisomerisation with diffuse light⁴ indicates that the resistance of an individual rod would be about 700 M Ω in the absence of coupling to other cells.

A noticeable feature of the presumed responses to single photons was their rounded shape. In contrast, the opening and closing of single channels in other preparations leads to rectangular-shaped changes in conductance^{8,15}. This may imply that a large number of channels are affected by each photoisomerisation or that a single channel fluctuates so rapidly between open and closed states that only the average behaviour is observed.

Responses to bright lights, such as that in Fig. 3d, occasionally showed suppression of the dark noise, similar to the effect seen with intracellular recordings^{6,7}. In one cell the variance measured in the band 0.2 to 5 Hz was 0.050 pA² in darkness and 0.017 pA² during a light which gave a saturating response of 13 pA. The difference power spectrum was broadly consistent with a Lorentzian of half power frequency 1.5 Hz. It is not yet clear whether such dark current noise arises from conductance fluctuations in the outer segment or from fluctuations in intracellular voltage arising from a noise source elsewhere in the cell.

This work was supported by grant EY-01543 from the National Eye Institute, USPHS.

Note added in proof: It has come to our attention that a similar method of recording from rod outer segments has been reported by Jagger¹⁶.

Transport mechanism operating between blood supply and osteocytes in long bones

WE show here that cyclic loading, as naturally occurring in long bones, produces a flow of liquids through canaliculi. The magnitude of such a stress-induced flow is so great that it significantly increases the efficiency of the transport mechanism operating between blood supply and osteocytes.

The present state of knowledge, according to the curricula in biology and medicine, describes the mechanism of supply of nutrients to Haversian bone cells (osteocytes) and disposal of the waste products from the cells by the process of diffusion^{1,2}. Diffusion is a very powerful mechanism in other areas of the body where, first, there is a short distance between the vessel and the

cell and, second, the cells are surrounded by fluid. The osteocytes of Haversian bone (Fig. 1a), however, are almost completely entombed in a calcified matrix except for the long and narrow canaliculi through which the nutrients and waste products must pass. Thus, diffusion is probably quite weak and it must be aided by another mechanism.

Assuming that bone is compressible and is loaded in compression, the volume of the canaliculus would decrease and thus pump the liquids out into the central vessel. After unloading, fresh nutrients will be drawn in from the Haversian canal into canaliculi (Fig. 1b). There is indeed much supporting evidence that cyclic loading of bone affects its mass; it grows thick and healthy. Immobilisation, bed rest or weightlessness, results in atrophy and in general loss of bone mass.

The proposed mechanism is examined here in greater detail. The lamellar structure of the Haversian system has been previously described and earlier studies established only that lamellae differ in the orientation of collagen fibres and perhaps in their mineral content. More observations were made recently by Vincent³, Ascenzi *et al.*⁴ and Boyde⁵. The pertinent information of these investigators may be summarised as follows.

Concentric cylinders of lamellae may differ from each other by their size, orientation of collagen fibres and ratio of mineral to

Fig. 1 a, Schematic representation of the microstructure of cortical bone¹. b, Simple model of stress-induced flow in the lacunar-canalicular system.

organic phases. Ascenzi *et al.*⁴ distinguished some of the lamellae as true lamellae, 5–7 μm wide, and some as interlamellar cementing zones, 1.5–2 μm wide. The latter displayed random orientation of collagen compared with the regular fibrous structures of lamellae.

Scanning electron micrograph of a fractured bovine bone treated with ethylene diamine, to remove the organic phase also revealed lamellar arrangements of phases in an osteon (Fig. 2). Similar observations were made on sectional specimens of bone treated with 95% hydrazine. It may reasonably be assumed that the empty spaces between the solid cylinders had a higher content of the organic phase, and any mineral phase present existed there in the classical form of discontinued crystallites which presumably dropped out on removal of the organic phase. Closer examination of the remaining mineral rings suggests a continuous polycrystalline structure (Fig. 3).

For the study of flow within the lacunar–canalicular network, organic material with suspended mineral was assumed to behave as a liquid, that is, capable of transmitting hydrostatic pressure. Thus, the Haversian system may be visualised as multiple concentric porous mineral cylinders separated by regions of liquid (Fig. 4). Such a structural arrangement can be easily analysed by a mathematical and physical model. It was also assumed that the pressure in the central cylinder would remain constant (equal to capillary blood pressure) and independent of flow through the canaliculi. The general concept and solution technique for axially loaded liquid-filled single and multiple concentric cylinders has been previously described in great detail (refs 6, 7).

After axial compressive loading of the model (Fig. 4), a hydrostatic pressure gradient is produced between the liquid regions. As flow occurs through the cylinders (canaliculi modelled as circular tubes), liquid on the inner side of the peak pressure moves radially inwards as in the simple model (Fig. 1b). Liquid on the outer side of the peak pressure, however, initially travels outwards and then, after $t = 0.0013$ s, inwards. Thus, in one-half of the loading cycle, the middle and outer areas of the model experience a two-way flow, whereas the inner areas only a one-way flow. This same pattern, opposite in direction, occurs after release of the load.

In both the simple and concentric cylinder models, it has been shown that cyclic stressing produces cyclic flows within the lacunar–canalicular network of the Haversian system. What remains to be shown is the order of magnitude of difference between the effect of the stress-induced flow and diffusion in transporting nutrients and waste products.

A set of calculations was performed for each liquid region to compare a common variable, the local displacement of a constant concentration, between a diffusion model and the stress-induced flow model for the period of 0.5 s, which approximates to one-half of a walking cycle, that is, a period of a normal loading of a long bone. The local displacement for the stress-induced flow model was calculated by assuming that the total volume change of that

Fig. 3 Portion of a lamella of the osteon in Fig. 2 illustrating polycrystalline arrangement of the mineral phase.

region and its outer regions flowed through the canaliculi of that region.

For the diffusion model, a linear concentration gradient of the diffusing matter varying from 100% in the central liquid region to 10% in the outermost liquid region was assumed. One-dimensional diffusion in a semi-infinite medium was considered, that is

$$C = C_0 [1 - \text{erf}(x/2(DT)^{1/2})]$$

The estimate of the diffusion coefficient, $D = 10^8 \text{ cm}^2 \text{ s}^{-1}$, was based on the results of the *in vitro* bone diffusion experiments of Amprino⁸ and Lang *et al.*⁹. The local displacement for the diffusion model was the distance that the assumed local concentration moved in 0.5 s. The ratio of the local displacement of the stress model to that of the diffusion model as a function of radius is given in Table 1.

Table 1 Comparison of local displacement values for stress-induced flow and diffusion models

Liquid region	Radius (μm)	Ratio: induced flow/diffusion
2	16	3,700
3	23	1,140
4	30	490
5	37	230
6	44	110
7	51	46
8	58	12

Although no direct calculation can be made relating fluid movement and diffusion in the stress induced flow model, it is felt that diffusion would be aided significantly by increased mixing caused by the very large relative motion of liquids through both the rough-walled canaliculi and the lacunae.

In addition to this very basic comparison, an examination of the pattern of the flow in Fig. 4 indicates that the reversed directions of flow in canaliculi during compression and relaxation cycle would produce additional mixing of liquids, thus aiding further the mechanism of diffusion. It is also reasonable to assume considerable mixing to occur in each lacunae until diffused product would reach most outwardly located osteocytes.

The mechanism of the radial motion of molecules through the canaliculi and lacunae is completely unknown. The osmotic behaviour of cell membranes and processes surely plays an important part. An approximation of the canaliculus to a round tube is also inaccurate. An electron microscope examination of the wall of the canaliculus reveals uneven and porous surfaces¹⁰. Thus, there may be many other factors affecting diffusion processes between the blood vessels and bone cells. This investigation demonstrates the existence of one very powerful aiding mechanism

Fig. 2 Fractured surface of a bovine osteon deproteinised with ethylene diamine.

Fig. 4 Stress-induced flow in the lacunar-canalicular system modelled as a number of concentric cylinders separated by regions of liquid (detailed calculations in ref. 7).

which should not be neglected when considering transport of molecules through the canaliculi.

Unstable protein mediated ultraviolet light resistance in *Anacystis nidulans*

CYANOBACTERIA are believed to have been precursors to eukaryotes during Precambrian evolution¹. It is also suggested that the oxygen evolved as a result of photosynthetic activity in these organisms, several of which are obligate photoautotrophs, was the major contributor towards the transition from anaerobic to aerobic atmosphere^{1,2}. It is, therefore, reasonable to expect cyanobacteria to have evolved in an environment with a relatively high flux of

solar ultraviolet light in the absence of ozone shield. This, presumably, could be possible with the evolution of efficient protective mechanisms or repair systems effective against damage by ultraviolet light. It is therefore not surprising that these organisms possess an extremely efficient photoreactivating repair system³. The presence of dark-repair in *Anacystis nidulans* has also been suggested by the isolation of mutants sensitive to ultraviolet light⁴. We present here physiological evidence for a dark-repair (or protective) system in this organism. A protein, unstable at least in the light, seems to be responsible for the resistance against lethal damage by ultraviolet light. This is observable in conditions of reduced photoreactivation achieved by a 24 h post-irradiation dark incubation, referred to here as 'dark-survival' following Asato, who showed that well within this period photoreactivability of damage by ultraviolet light is almost completely lost⁴.

Strain BD-1 *A. nidulans* was cultured and plated in synthetic medium, C-Mn, as described by Van Baalen⁵. The cells were grown in light (200 foot-candle (fc)) from tungsten lamps, at 35 °C in a shaker. Exponentially grown cells were used for all the experiments. The plates were incubated in the presence of 200 ± 10 fc of light from tungsten lamps and were maintained at 36 ± 1 °C in an incubator. After 5-6 d of growth the colony counts were taken.

Incubation of cells with chloramphenicol before exposure to ultraviolet light sharply reduced their dark-survival (Fig. 1). Almost the maximum reduction in the dark-survival at

Fig. 1 Kinetics of survival by *A. nidulans* on exposure to ultraviolet light during incubation in light in the presence and absence of chloramphenicol. Exponential phase cultures of strain *A. nidulans* BD-1 at a concentration of 10⁷-10⁸ cells per ml without further washing were divided into two fractions. In one fraction chloramphenicol was added to a final concentration of 5 µg ml⁻¹ (●). The other fraction contained no chloramphenicol (○). Both the fractions were incubated at 36 ± 0.5 °C in a water bath shaker. Light from tungsten lamps was incident at an intensity of 200 fc. At indicated time after the addition of chloramphenicol samples were diluted in the growth medium at 35 °C and spread on synthetic agar plates prewarmed to the same temperature. Plates with cells were exposed to 165 J m⁻² of ultraviolet light (254 nm) from Philips TUV15W germicidal lamp at an intensity of 11 J m⁻² s⁻¹. The control and ultraviolet light exposed cells were kept in the dark for 24 h at 35 °C. After the dark-incubation all the plates were transferred to light (200 ± 10 fc) at 35 ± 1 °C. After incubation in light for 5-6 d the colony counts were taken.

Fig. 2 Survival of *A. nidulans* on exposure to ultraviolet light when preincubated in visible light in the presence and absence of chloramphenicol (CAP), as function of post-irradiation dark-incubation temperature. Exponentially growing cells without further washing were incubated in light (200 fc) without (○) and with $5 \mu\text{g ml}^{-1}$ of chloramphenicol (●) for 3 h at $36 \pm 0.5^\circ\text{C}$ in water bath shaker. Control and treated cells were washed and resuspended in fresh growth medium at 35°C and 10 ml suspensions of each were immediately exposed to 330 J m^{-2} ultraviolet light. 1-ml aliquots of control and irradiated cells were transferred to thermally equilibrated tubes at indicated temperatures in the dark. After 24 h of dark-incubation at the respective temperatures the cells were diluted, plated and grown for colony counts as described in the legend to Fig. 1. The ratio of surviving fraction of untreated to chloramphenicol treated cells at the indicated temperatures is also shown (x).

35°C was achieved in about 3 h of chloramphenicol treatment. The extent of the dark-survival also depends on the post-irradiation temperature (Fig. 2). This dark-survival was significantly lower in the cells pretreated with chloramphenicol in the temperature range $20\text{--}40^\circ\text{C}$. The ratio of the surviving fractions of the untreated to the chloramphenicol treated cells was a function of the temperature of the dark-incubation, with a maximum at about 30°C . These results strongly suggest that some protein(s) normally present in the cell before the ultraviolet light exposure is involved in the dark-survival. The cells preincubated with chloramphenicol for 3 h or more are deficient in this protein suggesting its unstable nature. The higher survival at lower temperatures in Fig. 2 may be due to the arrest of (enzymatic) reactions leading to the loss of photoreversibility of the lesions which on subsequent incubation for growth in light may be removed by photoreactivation. When the chloramphenicol treated cells were exposed to photoreactivating light after ultraviolet light irradiation, their survival was comparable to untreated cells showing that the above protein(s) is not the photoreactivating enzyme. Incubation in the dark before ultraviolet light exposure is known to increase the dark-survival of this organism⁶. Chloramphenicol treated cells also showed a similar resistance when incubated in dark before ultraviolet light exposure. This unstable protein, therefore, may not have

a significant role in the development of the resistance of cells to ultraviolet light on preincubation in the dark.

The repair protein(s) described here is unstable in as much as the associated repair capacity is considerably reduced by the preirradiation treatment with chloramphenicol. In contrast, the same treatment does not measurably affect the photoreactivating capacity. A previous attempt to detect the presence of an unstable repair protein in yeast was unsuccessful⁷; in yeast pretreatment with nuclear specific protein synthesis inhibitor did not affect the liquid holding recovery⁷. In *Escherichia coli* an inducible repair protein synthesised after exposure of the cells to ultraviolet light has been detected⁸⁻¹⁰.

It is not clear whether this unstable protein has a role in unirradiated cells of *A. nidulans*. This organism may possess a constitutive or a visible light inducible repair pathway involving a protein which is independent of light for its action. Such a system could have a very important role in ensuring survival in an environment where photoreactivating system could not meet the challenge by a relatively high intensity of ultraviolet light. Regulation of repair processes by visible light has been suggested for eukaryotes^{11,12}. No specific mechanism is known.

I thank Dr S. K. Mahajan for critically reading the manuscript, and K. A. V. David, N. D. Shirke and G. Bhattacharjee for their cooperation.

Detection of casein messenger RNA in hormone-dependent mammary cancer by molecular hybridisation

THE growth and development of the normal mammary gland are regulated by the complex interaction of both peptide and steroid hormones¹. Whereas some breast cancers retain the hormone-dependent characteristics of normal mammary tissue^{2,3}, other tumours lose this responsiveness and grow autonomously. Following the pioneering work of Huggins⁴ on the hormonal dependence of both experimental and human breast cancer, investigators seeking a prognostic test have studied the relationship of specific oestrogen receptors to mammary cancer^{5,6} to the response of the tumour to endocrine ablation^{7,8}, and to the levels of other steroid⁹ and peptide hormone receptors^{10,11}. A superior marker for hormone responsiveness would, however, be a measurable product of hormone action rather than the initial binding interaction. In the mammary gland, casein synthesis has been used as a specific biochemical marker of differentiated function and hormone responsiveness. In the studies reported here, a specific complementary DNA copy (cDNA) of rat casein mRNA has been utilised to study the effects of hormones on the expression of differentiated function in chemical carcinogen-induced mammary adenocarcinomas. It is shown that casein mRNA as detected by cDNA may be a useful indicator of hormone dependence in experimental breast cancer. The cDNA probe was synthesised using as a template a 15S casein mRNA fraction

Fig. 1 Effect of hormonal treatment on the growth of DMBA-induced rat mammary carcinomas. Mammary adenocarcinomas were induced in 50-d-old female Sprague-Dawley rats by a single intubation of 20 mg DMBA. Tumours usually appeared 8–14 weeks after the administration of the carcinogen. *a*, Hormone dependence was assessed without ovariectomy by the single injection of an anti-oestrogen, nafoxidine 200 μ g s.c., given at the time indicated by the arrow. *b*, Hormone dependence of tumours was also determined by measuring the response to ovariectomy and the administration of hormones, either oestradiol benzoate (10 μ g every 3 d s.c. in sesame oil, ●), or oestradiol benzoate and prolactin (ovine, 35 IU mg⁻¹, (NIH-P-S12) 1 mg daily i.p., ○). Arrows indicate the time of ovariectomy (OVEX) followed by hormone administration.

purified 180-fold from a lactating RNA extract by chromatography on dT-cellulose and several precise sizing techniques^{12,13}. The template mRNA fraction represented greater than 90% casein mRNA, as estimated by specific immunoprecipitation of the total protein synthesised in the wheat germ assay, and by a careful analysis of its kinetics of hybridisation with the cDNA probe¹³. The specificity of the complementary DNA copy of the 15S casein mRNA has been demonstrated previously¹³. This cDNA probe

selectively hybridised to RNA from lactating tissue but not to rat liver poly(A)-containing RNA and the resulting hybrid displayed a high T_m characteristic of a well base-paired duplex. In addition, the rate of hybridisation of the casein-specific cDNA to various RNA preparations was directly related to the casein mRNA activity of these same preparations determined by a cell-free translation assay.

In these studies, 7,12-dimethylbenz(a)anthracene (DMBA)-induced rat mammary carcinomas were utilised as a model for hormone-dependent breast cancer^{3,4}. At least 80% of these tumours have been reported to respond to endocrine ablation and the levels of both oestradiol and prolactin receptors have been characterised previously¹¹. In addition, a limited number of autonomous mammary tumours induced in BALB/c mice have been screened for the presence of casein mRNA sequences. The amount of casein mRNA was quantified by analysing the rate of hybridisation of the complementary DNA with total RNA extracts of lactating and tumour tissue.

The characteristic growth response of the DMBA-induced rat mammary tumours to either ovariectomy and hormone administration or anti-oestrogen treatment are shown in Fig. 1. Ovariectomy resulted in a marked reduction in tumour size (Fig. 1*b*). Following either oestradiol administration or a combination of oestradiol and prolactin treatment, rapid growth was re-initiated. A single injection of nafoxidine, an oestrogen antagonist, also prevented the growth of hormone-dependent tumours for approximately 1 week without ovariectomy. (Fig. 1*a*). Following the return to the previous growth rate in the presence of the endogenous hormonal milieu, tumours were then removed and frozen before RNA extraction.

The hybridisation of the casein-specific cDNA to purified casein mRNA, RNA isolated from lactating tissue, and RNA isolated from some of the various hormone-dependent tumours is illustrated in Fig. 2. The 15S casein mRNA displayed a rate of hybridisation consistent with its high purity, and hybridised approximately 166 times faster than a total RNA preparation from 8-d lactating tissue. Both of these reactions occurred with the expected pseudo-first-order kinetics and proceeded to greater than 90% completion. Both the rates and extents of hybridisation of the

Fig. 2 Detection of casein mRNA sequences in hormone-dependent rat mammary carcinomas by molecular hybridisation. Tumours were excised, necrotic tissue removed and the remaining tissue rapidly frozen in liquid N₂. The isolation of total cellular RNA by the direct homogenisation of pulverised, frozen tumour tissue in a phenol-SDS solution at pH 8.0 has been described previously¹². Before hybridisation all RNA extracts were treated with Proteinase K (25 μ g ml⁻¹ at 37 °C for 10 min) followed by a final phenol-CHCl₃ extraction at pH 8.0. RNA excess hybridisations were carried out in 0.6 M NaCl, 0.01 M HEPES, pH 7.0, 0.002 M Na₂EDTA at 68 °C, and the extent of hybridisation was determined by S₁ nuclease as described previously¹³. The data are expressed as the percentage hybridisation compared with the log equivalent R_0t , the concentration of RNA (mol l⁻¹) times the time (s). The rates of hybridisation have been adjusted to the standard conditions of 0.18 M Na⁺ at 62 °C. The amount of DNA in the total nucleic acid extracts was determined by a standard diphenylamine assay and the rate of hybridisation adjusted accordingly. DNA did not contribute to the extent of hybridisation observed in any of the tumours at the R_0t values assayed¹³. The following typical hybridisation curves are presented in this figure. Hybridisation of ³H-cDNA with purified 15S rat casein mRNA (○), RNA isolated from 8-d lactating mammary tissue (×), RNA isolated from DMBA-induced tumours treated with oestradiol + prolactin following ovariectomy (●, △, ▽); treated with oestradiol alone following ovariectomy (□, ▲); and from tumours growing in a rat previously treated with nafoxidine (○, ▽).

Fig. 3 Quantification of casein mRNA levels in hormone-dependent DMBA-induced rat mammary carcinomas. A total of 31 DMBA-induced tumours were assayed for the presence of casein mRNA by molecular hybridisation as described in Fig. 2. The tumours were divided into four groups based on the treatment received (see Fig. 1). The data are expressed as a percentage of an 8-d lactating RNA preparation, which was run as a control during each group of hybridisations. The lactating RNA contained approximately 0.52% of the total cellular RNA as casein mRNA, equivalent to approximately 80,000 molecules of casein mRNA per alveolar cell¹³. The number of positive tumours containing casein mRNA divided by the total number of tumours assayed in each treatment group is given as a fraction beneath each group.

tumour RNA preparations were less than those observed for the RNA preparation from lactating tissue. The maximum hybridisation observed at saturation or achieved by a R_{0t} (the concentration of RNA, mol l^{-1} , times the time, s) value of 1,000 for the casein mRNA containing tumour RNA extracts ranged from 25–100%. Any RNA extracts which displayed less than 20% hybridisation by a R_{0t} value of 1,000 were considered not to contain significant amounts of casein mRNA.

The data obtained from these hybridisation experiments are summarised in Fig. 3. Significant hybridisation was observed for 22 out of 31 (approximately 70%) of the RNA preparations isolated from the hormone-dependent tumours. The levels of casein mRNA found in the hormone-dependent tumour RNA preparations ranged from 0–36%

of those found in the 8-d lactating RNA preparation, which had been estimated previously to contain as many as 80,000 molecules of casein mRNA per alveolar cell¹³. The highest levels of casein mRNA were observed in tumours of ovariectomised rats treated with both oestradiol and prolactin and the lowest in tumours growing under endogenous hormonal stimulation. The amount of casein mRNA present in tumours of animals treated with both oestradiol and prolactin was also greater than the level found in animals treated with oestradiol alone. This result is consistent with the role of prolactin in the induction of casein synthesis and casein mRNA in normal mammary tissue¹⁴. A wide range was observed, however, in casein mRNA sequence levels in the different primary DMBA-induced tumours even within a given treatment group. A similar variability in the levels of prolactin and oestradiol receptors has also been reported in these DMBA-induced tumours¹¹. This variability is most likely explained by the heterogeneity of cell types that exists within these tumours. Some cells may contain prolactin receptors and display the normal hormonal response, whereas others may either lack prolactin-binding sites or display an altered response. Two such distinct populations of cells have actually been identified in DMBA-induced mammary tumours by autoradiographic localisation of prolactin receptors using ¹²⁵I-prolactin¹⁵.

Whereas the majority of the DMBA-induced mammary adenocarcinomas in Sprague-Dawley rats are dependent on hormones for growth, those which appear in BALB/c mice are characteristically hormone-independent. The molecular basis for this autonomy and the difference in response of related species to the same chemical carcinogen are not well understood. Several transplantable mouse mammary tumour lines were also screened for the presence of casein mRNA sequences. Because of the previously reported sequence divergence of mouse and rat casein mRNAs¹³, a homologous cDNA probe was synthesised using a purified 15S mouse casein mRNA fraction as the template for avian myeloblastosis virus RNA-directed DNA polymerase. This cDNA probe displayed similar hybridisation kinetics with the purified mouse 15S casein mRNA and a total RNA preparation obtained from lactating mice as previously observed for the rat cDNA and mRNA fractions (Fig. 4). In addition, casein mRNA sequences were detected in RNA extracts obtained from 14-d pregnant mouse mammary tissue at levels less than one-fifth those observed during lactation, illustrating the sensitivity of the hybridisation assay. In none of the three autonomous mouse mammary tumour RNA samples tested, however, was any significant hybridisation detected. This assay is capable of detecting

Fig. 4 Measurement of casein mRNA sequences in hormone-dependent mouse mammary tumours. The mouse mammary tumours used in these studies were transplantable lines originally induced by DMBA administration to BALB/c mice. These tumours grew equally well in intact female or ovariectomised animals. Hybridisation of mouse ³H-cDNA with purified mouse 15S casein mRNA (▲), RNA isolated from a 10-d lactating mouse (Δ), RNA isolated from a 14-d pregnant mouse (●) and RNA isolated from three different transplantable lines of mouse mammary carcinomas induced with DMBA (○, ◇, □).

casein mRNA sequences at levels of less than at least 0.1% of the normal lactating gland. Thus, these three tumours seem to represent variants, which have lost the hormonal responsiveness characteristic of the normal mammary gland and the accompanying expression of differentiated function.

The absence of casein mRNA sequences in the hormone-dependent mouse mammary carcinomas is consistent with the autonomous growth of these tumours. The failure to synthesise casein mRNA in response to endogenous hormones may reflect the absence or low levels of oestradiol and prolactin receptors in these cells¹¹. A more thorough examination of other tumour variants, especially receptor-positive cells which are unable to synthesise casein, may help elucidate the mechanisms regulating casein synthesis. A larger selection of both hormone-independent and dependent rat and mouse mammary tumours should be screened before a definitive correlation between the presence of casein mRNA sequences and hormone independence of mammary tumours can be ascertained. The detection of casein mRNA in hormone-dependent rat mammary carcinomas in this study, however, is consistent with the previously reported expression of normal, differentiated function in both experimental^{16,17} and human breast cancer¹⁸⁻²⁰. In addition, prolactin-inducible casein mRNA activity has also been detected recently in experimental breast cancer using a cell-free translation assay²¹. In conclusion, the data presented in this communication suggest that casein mRNA may be a useful molecular marker for determining hormone dependence, in addition to the presence of steroid and peptide hormone receptors.

We thank Mr David Cooke, Ms Carol Waugh and Ms Gail Brady for assistance. Drs William McGuire and Daniel Medina kindly provided some of the DMBA-induced rat and mouse mammary carcinomas, and some of the nafoxidine-treated animals were provided through the courtesy of Ms Cheryl Watson and Dr James Clark.

A theory for genetic regulation by chromosome folding

This theory to explain gene expression in higher organisms is based on the spatial re-arrangement of genes by directed, specific folding of the chromosome. Tissue-specific differences in genome structure exist¹ and profound modulation of genome structure can occur during differentiation². It is postulated that specific proteins recognise specific sequences in double-stranded repetitive DNA and that, as a consequence, the structural genes encompassed by these repetitive sequences become accessible

to the transcribing proteins. Transcription and translation then result in synthesis of proteins characteristic of the particular differentiated state. The interactions of metals and other ions with repetitive DNA (ref. 3) may be important in this recognition.

The model is further described in the following example where S_1 , S_2 and S_3 are structural genes specifying proteins P_1 , P_2 and P_3 and R_1 , R_2 and R_3 are repetitive sequences. Suppose that a sequence of DNA is

$$R_1 S_1 R_1 \dots R_2 S_2 R_2 \dots R_3 S_3 R_1$$

and that P_3 is a tissue-specific recognition protein that initiates and stabilises the association of double-stranded repetitive sequences R_1 with each other. These R_1 sequences need not be identical, but if they are identical they must be orientated in opposite directions (Fig. 1). This results in a localised distortion and/or unwinding of the DNA double helices (perhaps through the formation of a localised four-stranded structure) which is transmitted to the encompassed DNA, thus loosening the 'nucleosome' structure and making the DNA available for transcription. Thus both S_1 and S_3 , but not S_2 , are transcribed and translated giving proteins P_1 and P_3 characteristic of the particular tissue. The presence of protein P_3 will maintain the particular differentiated state. Such an arrangement of repetitive and unique DNA is consistent with the data (but not the analysis) of Davidson *et al.*⁴

Since most proteins are synthesised in more than one tissue, it is necessary to postulate that a structural gene may have more than one associated repetitive sequence. This will result in a continuum of repetition frequency classes, the frequency of each is dependent on the number of different cell types in which its associated structural gene is expressed. For example, $R_1 R_3 S_1 R_1 R_3 \dots R_2 R_3 S_2 R_2 R_3 \dots R_1 S_3 R_1$. Thus, in different tissues the genes expressed are: (a) S_1 and S_2 ; (b) S_2 ; (c) S_1 and S_3 . Such an arrangement of repetitive and unique sequences is suggested by Cech and Hearst⁵. Where several sequential genes are coordinately expressed in a given tissue, the group will be encompassed by the appropriate repetitive elements.

Development of the differentiated state can also be explained. For example, suppose cell a differentiates to give cell b which gives rise to the mature cell c. The genome of cell a is stabilised in its specific conformation by protein X and produces proteins A, B and C. At cell division X is broken down and nuclear reprogramming occurs⁶. Protein C thus has access to the genome and stabilises it in the conformation characteristic of cell b, which produces proteins D, E and F. At the next reprogramming, protein F has access to the genome and stabilises it in the conformation characteristic of cell c which produces proteins F, G and H. The continuing presence of F ensures the maintenance of the differentiated state.

Fig. 1 Interaction of tissue-specific recognition protein P_3 stabilises the association of double-repetitive sequences R_1 with each other. a, Identical R_1 sequences; b, non-identical R_1 sequences. As a result, structural genes S_1 and S_3 , but not S_2 , are made available for transcription.

Such transcription active regions may be equivalent to the interbands of dipteran polytene chromosomes⁷ and the 'loops' observed in lampbrush chromosomes⁸. Such structures are dynamic in that they show developmental and tissue-specific differences in size and configuration⁹.

I thank Dr K. G. H. Dyke for criticism of the manuscript.

Water binding by antifreeze glycoproteins from Antarctic fish

Low molecular weight glycoproteins isolated from serum of Antarctic fish have been shown¹ to be responsible for freezing point depression which permits survival at temperatures down to -1.9°C . The principal active antifreeze glycoprotein (AFGP) of several Antarctic species consists of a repeating tripeptide Ala-Thr-Ala with a disaccharide galactosyl-*N*-acetylgalactosamine linked to the threonine residue^{2–4}. The AFGP is more effective in freezing-point depression on a weight basis than NaCl and several hundredfold more effective than ordinary proteins². Melting point, however, is virtually unaffected by the AFGP⁵. We have investigated the possible role of protein-bound water in the unusual antifreeze activity of the AFGP. Ordinary proteins such as bovine serum albumin, haemoglobin, and lysozyme show hydration levels of about 0.4 g H₂O per g protein⁶. This water does not freeze at temperatures down to -35°C , but is sufficiently mobile to produce a measurable proton magnetic resonance signal. Quantitative determination of the amount of this 'bound' water is therefore possible in frozen protein solutions⁷. We have used this technique to examine water binding by the AFGP over a range of temperatures below the freezing point of bulk water.

Antifreeze glycoproteins 1–6 (ref. 2) were isolated from *Dissostichus mawsoni* (Norman) at McMurdo Sound Station, Antarctica and purified by DE-22 cellulose ion-exchange chromatography. The product was dialysed exhaustively against distilled water and lyophilised. Samples for magnetic resonance were prepared in 0.01 M KCl at concentrations of 25–100 mg ml⁻¹ determined by weight and ultraviolet absorbancy. Solutions of standard globular proteins, bovine serum albumin (Schwarz-Mann, crystalline, 100%) and human oxyhaemoglobin (gift from R. Banerjee) were prepared similarly. Nuclear magnetic resonance (NMR) spectra were recorded on a Perkin-Elmer R12 spectrometer operating at 60 MHz. No accumulation procedures were necessary. The samples in commercial NMR tubes were cooled from room temperature in 5° steps to -5°C . At this temperature solvent alone froze and the proton resonance signal disappeared completely. In the case of the protein solutions which supercooled, bulk water freezing was induced by lowering the instrument temperature control to -20°C until the first indication of loss of signal was observed (about 2 min). The control was returned to -5°C and signals were followed until equilibrium (constant peak area and line width) was achieved. The time dependency of the signal response was followed with each subsequent change of temperature in 5° increments to -40°C (cooling curve) and in the return to the melting temperature of the solution (warming curve). Peak area stabilised in about 15 min, line width

Fig. 1 Amounts of 'bound' (unfrozen) water in protein solutions at temperatures below the freezing point of bulk water. Open symbols represent data taken during cooling from -5°C ; closed symbols are data collected during warming. ∇ , Δ , AFGP; \circ , \bullet , bovine serum albumin; \square , \blacksquare , human haemoglobin.

in about 30 min, after a temperature change. The reported data were obtained after equilibration for 60 min; in these conditions line widths for cooling and warming coincided except in the case of the AFGP above -10°C . Line width values represent the width at half-height of the absorption curves. Areas were calculated as the product of line width and height and were converted to absolute values for hydration by comparison with a standard water sample (4.5 M LiCl, 0.01 M MnCl₂)⁷.

Figure 1 presents hydration results for the three proteins studied during cooling from -5 to -35 or -40°C and subsequent warming to -2°C . Amounts of unfrozen water were directly proportional to protein concentration in the range studied. In the case of the two globular proteins identical results were obtained during cooling and warming. At temperatures of -20 to -35°C the hydration averaged 0.40 g per g protein, in agreement with previous studies^{8–9}. In the AFGP, hydration at the low temperatures is 0.55 g per g protein; above -15°C hysteresis in the temperature dependency is observed. During cooling, hydration values as high as 1.1 g per g protein are observed, whereas with warming values of about 0.6 g per g are found, as in the two protein standards.

Line width data show the expected exponential increase with decreasing temperature (Fig. 2). Arrhenius activation energies are 4.0, 6.5 and 7.7 kcal mol⁻¹ for the AFGP, haemoglobin and serum albumin, respectively. The results for the two standard proteins are thus in good agreement with previous values for activation enthalpies of protein-bound water: 7.3 kcal mol⁻¹ for haemoglobin (from dielectric relaxation)¹⁰ and 5.0 kcal mol⁻¹ for BSA (from proton resonance in frozen solutions)⁸. The result obtained for the antifreeze glycoprotein falls within the range observed for polysaccharide hydration, 3.6–4.8 kcal mol⁻¹ (ref. 11). Estimated activation entropies^{8,9} in this study are -9 e.u. for AFGP, $+4$ e.u. for haemoglobin, and $+9$ e.u. for bovine serum albumin. Comparison of results for the three proteins suggests that the higher level of hydration in the AFGP is associated with somewhat weaker binding, presumably fewer hydrogen bonds, and a less structured environment.

Relaxation behaviour in the frozen AFGP solutions during cooling was suggestive of a two-phase system with slow exchange¹². Thus, at -5°C a sharp resonance of line width about 100 Hz seemed to be superimposed on a broad band of width 600 Hz (Fig. 3), merging at lower temperatures. Both were distinguishable from bulk water which, before its freezing by means of the cold pulse, showed a line width less than 10 Hz. The additional component of unfrozen water in the AFGP apparently represents a category intermediate between Type I (bulk

water) and Type II (bound water)⁹. In quantitative terms the 100 mg ml⁻¹ AFGP solution at -5 °C contains about 90% Type I water, 5% Type II water, and 5% additional unfrozen water. Type III, irrotationally bound water⁹, is not measurable by this technique, but is anticipated to be less than 0.1%.

The level of Type II water in the AFGP seems to be consistent with its chemical composition. On the basis of hydration values of 1.5 H₂O/alanine residue and 2 H₂O/threonine residue¹³, hydration of 0.37 g per g protein would be predicted for the copolymer (Ala-Ala-Thr)_n. Since the polypeptide accounts for 39% of AFGP weight², it would therefore contribute 0.15 g H₂O per g AFGP to the total hydration. Hydration of the sugar portion of the molecule would have to be 0.66 g per g carbohydrate to account for the remaining AFGP hydration. This figure is similar to the value of 0.59 g per g reported for Agarose¹¹. The magnitude of the line width for the Type II water in the AFGP is consistent with an unstructured conformation of the molecule, as shown by circular dichroism² and confirmed for the samples used in this study. Signal broadening has been observed in urea-denatured bovine serum albumin⁹ and in random-coil polypeptides⁹.

Of particular interest is the possible significance of either the Type II water or the additional unfrozen water in the AFGP relative to freezing-point depression. AFGP occurs as several molecular forms in fish plasma at a total concentration of about 25 mg ml⁻¹; the active forms studied here account for up to 10 mg ml⁻¹ (ref. 2). Thus, the amount of water bound by the AFGP in plasma represents only 1% of total water. Nevertheless, the similarity in temperature-dependent hysteresis of the resonance data and that of the freezing-melting behaviour of the AFGP¹⁴ suggests a possible role for this water in the antifreeze activity. Studies of partition of the AFGP in frozen solutions indicate that the AFGP molecules are themselves incorporated into ice during freezing¹⁵,

Fig. 2 Arrhenius plots of line width data for unfrozen water in protein solutions. ▽, ▲, AFGP; ○, ●, bovine serum albumin; □, ■, human haemoglobin.

Fig. 3 Proton resonance spectra of unfrozen water in solutions of the antifreeze glycoprotein at -5 °C (a), -8 °C (b) and -10 °C (c).

although they do not affect other freezing characteristics such as salt compartmentalisation¹⁶. It has been suggested that AFGP may prevent ice propagation by direct binding to ice surfaces, thus increasing surface free energy or simply coating the ice with a barrier of unfreezable water¹⁷. Normal protein-bound Type II water is apparently not effective in freezing-point depression, as evidenced by the absence of this activity in ordinary proteins². The explanation for AFGP activity, however, may lie in the elevated levels of water that is resistant to freezing, and in the extended conformation of the molecule which serves to optimise surface contacts with ice crystals. Comparative studies of water binding in model polysaccharides and in related fish glycoproteins which lack antifreeze activity should shed further light on the activity of this unusual protein.

reviews

The problematique

Eric Ashby

The Human Quality. By Aurelio Peccei. Pp. 214. (Pergamon: Oxford and New York, 1977.) Paperback, £3.25; \$6. Hardback, £6.50; \$12.

To write about this book as a reviewer is easy, but as a critic is difficult. I shall try to do both.

The early part of the book is an artless life-story of a modest, sincere, and courageous man. Aurelio Peccei was a freedom-fighter in the Resistance in Italy, imprisoned at one time by the Nazis. He then became a highly successful industrialist. It is ironic, in the light of his present activities, that his industrial success was to provide large numbers of mass-produced automobiles which polluted Europe and—through Peccei's special efforts—Latin America.

But Peccei's conscience survived this material success and he turned in 1957 to something with a dash of altruism added to industrial acumen: an engineering and economic consultancy which was to do work in developing countries on a non-profit-making basis. It was not a Pauline conversion exactly, for Peccei still maintained his connections with the manufacture of automobiles, but he had come to the view that multinational companies have a responsibility to society above that of making profits for their shareholders. By the 1960s, his family being now grown up and his level of affluence being adequate, Peccei found himself free to reflect on human destiny.

The rest of the book describes Peccei's reflections and the practical steps he has taken to disseminate them. The most significant of these steps was the formation of the Club of Rome, which is an informal group of people who are concerned with what they call the *problematique*. The *problematique* is (Peccei writes) the "intractable tangle of difficulties" which constitute the present "predicament of mankind."

That there are intractable difficulties facing industrial societies and the developing nations no-one questions for a moment. But that Peccei and the Club of Rome are the first people to have realised this, is nonsense. The Club (writes Peccei, observing that "we know incredibly little about our

changed conditions") is "the first to rebel against this well nigh suicidal ignorance." This claim to priority is just one of a string of unacceptable assertions in the book. Has the Club of Rome not heard of H. G. Wells, Aldous Huxley, George Orwell, Lewis Mumford, Bertrand de Jouvenal? Were they not aware of the *problematique*?

Peccei offers a somewhat querulous defence of the best-known project of the Club of Rome, which was to sponsor the book *Limits to Growth*. The warning in this book, that continued exponential growth would lead to collapse, was (Peccei writes) "denounced as nothing more than a heretical and misinformed libel." This is a grossly inaccurate way to describe the sober and careful criticism which *Limits to Growth* received. Peccei does nothing to refute these criticisms; indeed he does not even mention what the criticisms are: not a word about the reasoned indictments from the University of Sussex or the World Bank. These critics were not (as Peccei suggests) defending the "sacred cow of growth" nor were they under the impression (as Peccei suggests) that the Club of Rome advocated zero growth. The critics were simply exposing the spurious assumptions which had been fed into MIT's computer. In a later chapter, but without acknowledging the debt which the Club of Rome owes to these critics, Peccei concedes some of their criticisms. "Perhaps," he writes, "science and technology are capable of placing at mankind's disposal the immense resources required. . . ."

It is over 50 years since Raymond Pearl published data on the sigmoid curves of population growth and discussed some of their consequences. The Club of Rome has performed a useful service in stimulating popular interest in the climacteric of modern society: the transition from accelerating growth rate with positive feedback to decelerating growth rate with negative feedback; and I am willing to acknowledge that the issue had to be made sensational in order to capture public attention. But the basic strategic error which the Club has made (and which Peccei makes even more egregiously) is to deflect people from paying attention to thousands of mini-

solutions to mini-problems (which is the way society is most likely to survive this transition) by dangling before them one Comprehensive Maxi-Solution.

Assertions about the maxi-solution occupy most of the space in Peccei's book. They are offered in the tedious platitudes which are the despair of people who are seriously engaged in the minute particulars of trying to improve the condition of society. "[S]ociety must see to it that *all* the benefits which the system can provide—including goods and services—are actually put at the disposal of *all*." Mankind "must undergo" a process of "total re-education." It is the use of the word "must" which riles me. Even if you accept the premise—that "must" implies "ought"—there are two consequential questions which follow the use of the word "must"; one is: "How?" The other is: "Imposed by whom?" Neither Peccei nor the Club of Rome offer any answers to these two questions. Without answers, these intoxicating declarations simply save people the trouble of considering far more important problems, such as how to see to it that *some* of the benefits of the system can be put at the disposal of *some* people, and that in place of the airy policy of total re-education for *everyone* (New York stockbrokers, Italian politicians, Indian peasants, Ghanaian cocoa farmers, Moscow policemen!), there is encouragement for thousands of people who are trying to do a little re-education for a few.

So I reject Peccei's whole approach to the predicament of mankind on the simple criterion that these vague and sweeping clichés which he offers as the recipe for achieving social justice are as impotent to solve the *problematique* as similar vague generalisations would be for the production and sale of automobiles. But—and here I am in complete agreement with Peccei—the *problematique* (much as I dislike the word) does stand for something real which confronts governments all over the world. What can take the place of Peccei's sincere but futile gestures to mankind at large? I think there are modest and much less colourful alternatives. It would be more effective if diagnoses of the predicament of mankind were to separate

clearly what *is* (that is, to get the facts straight) from what *ought to be* (which is legitimate ethically provided you say *why* it ought to be); and never to proceed to "*must*", for on that way lies compulsion, dictatorship, the rule of Leviathan. A wise assumption would be that social attitudes cannot be changed except incrementally, and that there are "tolerance limits", so to speak, to the magnitude of a change which people will contemplate and be prepared to accept. Any proposal which lies outside these tolerance limits is rejected; it creates resentment, sales resistance, is (in modern jargon) counter-productive.

And, finally, all attempts to define goals for mankind are likely to be mirages, vanishing as one approaches

them. There is another way to move toward goals: that is not to demand a grandiloquent metamorphosis of mankind, but instead to encourage little groups of people all over the place to make wise choices over small changes in society. For it is one lesson of history (and it would do the Club of Rome no harm to read a little history) that ends are continually being re-defined by the means being used in groping toward those ends; and it is another lesson of history that *men and women* do respond to messages which lie within their range of understanding, but *mankind* is deaf to all messages. □

Eric Ashby is at present Walgreen Professor of Human Understanding at the University of Michigan.

GC-MS system

Fundamentals of Integrated GC-MS. Part III: The Integrated GC-MS Analytical System. By B. J. Gudwinowicz, M. J. Gudwinowicz and H. F. Martin. Pp. vii+603. (Dekker: New York and Basel, 1977.) SFr.190.

THIS third part of the text on analytical chemistry was written in mid-1976 and surveys knowledge about the integrated gas chromatography-mass spectrometry (GC-MS) system up to that date.

The first chapter deals with basic vacuum technology and the interface between the GC and MS, seeks to provide enough of a mathematical treatment of gas flow characteristics to permit an understanding of the problems associated with interfaces to be appreciated. All of the usual enrichment devices are discussed in detail and their characteristics compared. The authors have made excellent and very full use of tables, graphs and drawings of apparatus as well as including in the text many references to original work. The chapter contains 181 pages with 18 tables, 88 figures, 263 mathematical equations and 221 references.

The middle chapter deals with the methods which are available to optimise the operational parameters of each separate part of the integrated GC-MS analytical system. The authors consider each operational parameter in turn and deal with the optimisation of carrier gas flow rates, injection systems, the thermostability of liquid phases, chromatography columns of various types, inlet and effluent splitters, separator enrichment factors and characteristics, source temperature and pressure, ionising potentials, sensitivity, scan rates, dynamic resolution, ratio recording, and the use of peak matching techniques to measure the

accurate mass of fragment ions during GC-MS scans. This long chapter is fully illustrated and well referenced, containing 202 pages with 29 tables, 96 figures and 484 references.

The final chapter deals with the role of a mass spectrometer as a GC detector and the data processing of the mass spectral results. The role of the ion monitor in producing a total ion monitor (TIM) graph is discussed, and multiple ion monitoring and single ion monitoring techniques are reviewed in detail. Several examples of the use of mass fragmentography techniques for the analysis of biological samples are described and the sensitivity of detection and quantification using single ion monitoring are discussed.

The history of the application of data processing techniques to mass spectrometers is reviewed and the use of these systems for the calculation of the accurate masses and the molecular formulae of fragment ions, and their display in terms of element maps, is described. Repetitive cyclical scanning GC-MS-COMP systems are described where the mass and abundance information is stored in disc systems ready for regeneration in the form of individual mass spectra, outputs from library search routines or mass chromatograms. The final chapter contains 140 pages with 15 tables, 68 figures and 171 references.

The authors have provided a book which is a mine of information for those involved in, or about to embark on this field. It is prepared to a high standard and is well indexed. It is a 'must' for every GC-MS laboratory but it is priced (190Fr=£46) well beyond the resources of most individuals.

James A. Ballantine

James A. Ballantine is Senior Lecturer and operator of a GC-MS system in the Chemistry Department of the University College of Swansea, UK.

Statistical mechanics revised

Statistical Mechanics. Second edition. By J. E. Mayer and M. G. Meyer. Pp. 491. (Wiley: Sussex, New York, Sydney, Tokyo, and Mexico City, 1977.) £17.50; \$29.

A CLASSIC BOOK revised by its author 37 years later for a second edition has to be approached with the respect one would normally reserve for, say, a fine old whisky. This respect is indeed deserved, for this book has retained its clarity, relevance and coverage. It has nevertheless lost some of the quality of the first edition: the small print—an author's whisperings into a reader's ear—has gone. So has the author index; so have the problems and the glossary. The effect is that the material, though necessarily altered, covers the same number of pages as the first edition. I bought my 1948 copy, however, for one-seventh of the present price.

Turning to the contents, substantial parts of the book are unchanged; for example, the early chapters and also the treatment of electric and magnetic fields. The discussion of black-body radiation is postponed to the quantum theoretical part, as it was in the first edition, and so comes rather late (p368) for so important a topic. On the other hand, new sections on computer experiments (p320), on the coupling of nuclear spins to electrons and on spin echo, up-date the book in the author's lively style. Some unexpected references are left, for example (p38), one to Gibson's Amsterdam thesis of 1933, which readers are unlikely to want to look up to check on the viscosity values for hydrogen. A "constant entropy paradox" is named, stated, and resolved, but the simple lesson that coarse-graining is to some extent responsible for entropy increase is not very explicitly drawn. There is not much on stability or negative temperatures and on p106 the author might have noted that heat capacities *can* be negative (in gravitational systems).

This book, written by two great experts in the field, and now revised with extreme care by one of them, remains a good introduction, is a source of much useful information, and should enjoy continued popularity.

Peter Landsberg

Peter Landsberg is Professor of Applied Mathematics at the University of Southampton, UK.

Heterocyclic compounds

Stereochemistry of Heterocyclic Compounds. Part 1: Nitrogen Heterocycles. By W. L. F. Armarego. Pp. 443. Wiley: London, New York and Sydney, 1977. £27; \$45.

DR ARMAREGO'S aim is to survey the entire stereochemistry of heterocyclic compounds, excluding most natural products, in two volumes. He has chosen to do this by referring freely to specialised reviews and other secondary sources, thereby avoiding duplication of effort and leaving himself free to give quite detailed discussion to the remainder of the subject, with emphasis on recent work. This approach clearly adds to the value of the book to the specialist but runs the risk of bittiness and lack of balance for the more general reader. Fortunately, Dr Armarego's style and wide-ranging interest in his subject save the book from these dangers, and large parts can be read with enjoyment and a sense of continuity.

This volume is concerned with compounds with nitrogen as the only heteroatoms in the rings and is divided into a short introductory chapter and

three very long chapters with compounds classified by ring size: chapter 2 covers three-, four-, and five-membered rings, chapter 3 six-membered rings, and chapter 4 the larger rings. Each chapter is subdivided into increasingly complex classes of compounds in a way that makes it generally easy to locate information without working through the detailed table of contents.

A book of this type must be up to date, reliable and uniform in its coverage of the original literature, clear in its diagrams, and concordant with currently accepted theory in its interpretations of the properties of the compounds described. In most respects Dr Armarego's book meets these requirements well. The references are very full for the period from 1965 to about the middle of 1975. A check on the references in chapter 3 showed that the average number each year for 1965 onwards is about six times as high as for 1964 and earlier. The abrupt change in the frequency of references suggests the possibility that Dr Armarego's book may have gaps in respect to the earlier literature but I have not found any that are important and not indirectly covered by the references to secondary sources. Occasionally there is a lack of balance: for example, Kipping's work on 2,3,5,6-

tetramethylpiperazine in the 1930s is described in some detail when a reference to Harris and Sheppard's conclusive NMR study in 1955 would have been sufficient. In contrast, the diazabicyclo[3.3.1]nonanes are dismissed very briefly. This section contains a rare but bad example of chemical misunderstanding because the 'normal' amide carbonyl group in 3-isopropyl-2-oxo-1,3-diazabicyclo[3.3.1]nonane is regarded as a violation of Bredt's Rule and is inappropriately contrasted with the ketonic carbonyl group in 2-oxo-1-azabicyclo[2.2.2]octane. The formulae are usually clear and well drawn, particularly when this is most important as with bridged and caged polycyclic systems, but there are, unfortunately, some very distorted drawings of fused six-membered rings (notably, formulae 260 and 296 in chapter 3) that result from the uncritical use of stencils.

Dr Armarego has been very successful in realising his aim. This book will be bought by many chemists with interests in stereochemistry or heterocyclic chemistry, as well as by all chemical libraries. **M. J. T. Robinson**

M. J. T. Robinson is a University Lecturer in Organic Chemistry at the University of Oxford and a Fellow of Magdalen College, Oxford, UK.

Weak interactions

Weak Interactions. By David Bailin. Pp. ix+406. (Chatto and Windus: London, 1977.) Paperback £9.

THE subject of weak interactions has developed very rapidly in the past decade. As a result there is a fairly wide and growing gap between good old textbooks, such as the well known book by Okun, and the moving frontiers. Since there are no signs that the motion of the frontier is slowing down, it is wise to educate graduate students in particle physics in the field of weak interactions. David Bailin was aware of this real problem and this book is his answer to it.

The book starts with a lengthy introduction to the Dirac equation and the construction of invariant amplitudes for fermions, and then discusses in detail leptonic, semileptonic and non-leptonic weak interactions as well as CP violation and unified gauge theories.

The new knowledge gained in the past decade is indeed covered by Bailin's book, which is useful as a guide to what is known and as an introduction to the literature. Its main strength lies in the material which is covered and the detailed elaboration

of computational details. I could find very few misprints and no errors of calculation.

The emphasis on calculations is also the source of the main weakness of the book: it is lacking in pedagogy. There is much more material than could be covered in a one-year course. The author could, however, have avoided stressing hard computation rather than easy insight. Many topics are discussed in a way which, though correct, are likely to be difficult for beginners. For example, SU_3 and the Cabibbo angle are introduced in an abstract fashion starting with the structure constants f_{ijk} of the algebra. It is much more easy to start with a quark model and introduce the Cabibbo rotation at the level of the quark currents and only talk about SU_3 afterwards. This way is also easier to generalise to a larger number of quarks—a contemporary problem.

I recommend Bailin's book to all those who want to become familiar with modern developments in theoretical technology for weak interactions. The publishers must anticipate a huge increase in graduate student grants, judging from the price of this book.

Vector analysis

Vector Fields: Vector Analysis Developed Through Its Applications to Engineering and Physics. By J. A. Shercliff. Pp. 329. (Cambridge University: Cambridge and London, 1977.) Hardback £13.50, paperback £4.25.

THIS book is stimulating and occasionally irritating; but few stimulants are without their side-effects. It is aimed at physicists and engineers at the equivalent of British second-year undergraduate level. Teachers of engineering may be happier with it than teachers of physics, although many physics students might find that it taught them more than would a more conventional approach. The approach is unconventional, to this physicist at least, because it fuses the entire content of a classical electromagnetic theory course and of a hydrodynamics course in order to illustrate the tools and methods of vector analysis.

The introductory chapters certainly would not replace proper courses on basic electricity and magnetism or on vectors. The summary is brief and might be rather obscure to, for instance, a student whose knowledge of vectors was based on 'modern mathematics'. The argument is pictorial and intuitive, with some stress placed on a rather woolly property which all authentic vectors are supposed to have; 'cosine quality'. Someone who has played with scalar products, work integrals and components of forces will grasp 'cosine quality' straight away, just as someone who knows Fleming's left-hand motor rule will understand how magnetism is 'electricity looked at sideways'. The good thing about this cavalier treatment is that it should give the student a feeling for the eventual simplicity of material which he may have found heavy-going in the first year.

The next chapter is on line and surface integrals, assuming some knowledge of partial differentiation and of Taylor's theorem. Ampere's law, the Biot-Savart law and various aspects of current electromagnetism are followed by volume integrals, with illustrations from simple plasma theory. Then comes 'A crisis in electromagnetic theory', a rather wordy treatment of the arguments leading to the concept of displacement current. The stage now seems to be set for the derivation of Maxwell's equations. But no; this consummation is delayed for another five chapters. Divergence and gradient must be introduced; then Gauss' theorem, Laplace's equation, a variety of applications to hydrostatics, fluid flow and heat flow, Poisson's and Helmholtz' equations with examples including the

criticality condition in a nuclear reactor. The treatment of waves and of the superposition principle is surprisingly sketchy after the detail given to many other topics.

Curl comes next, with a great deal of illustrative detail in hydrodynamics, leading to Stokes' theorem. Then, at last, we are ready for Maxwell's equations, followed by discussions of the skin effect, electromagnetic waves and the Poynting flux. The final chapter is on 'Integrals in fluid mechanics', beginning with derivations of Kelvin's and Helmholtz' theorems and applying them to such problems as the jet from an orifice, flow over an infinite airfoil and the lift and drag properties of an aircraft wing.

The book is illustrated with a large number of clear, simple line drawings.

Search for life

Chemical Evolution of the Giant Planets. Edited by Cyril Ponnamperuma. Pp. 240. (Academic: New York and London, 1976.) \$11.50; £8.15.

THIS book contains the invited lectures presented at the first of a series of colloquia to be organised by the Laboratory of Chemical Evolution at the University of Maryland, aimed at bringing together scientists for formal and informal discussion on topics pertinent to chemical evolution. The meeting, held in October 1974, was stimulated by the availability of data from NASA's Pioneer 10 and 11 and attended by astronomers, chemists, biologists and engineers, involved with, or interested in, the outcome of those missions. The overall theme of the discussion was intended to consider whether conditions prevail in the atmospheres of the giant planets which are conducive to chemical synthesis, or able to support life of a terrestrial nature. The title of the volume may be to some extent a misnomer since many of the authors did not restrict themselves to the location suggested. The outer planets in general, Mercury, Venus, Mars, meteorites, comets and the satellites of Jupiter and Saturn, particularly Titan, are freely discussed.

The book consists of sixteen papers by twenty authors; its content may be broken down into several general subject areas. T. Gehrels, D. M. Hunten and T. Owen provide essential background information concerning atmospheric composition, structure and chemical composition. W. F. Libby, J. S. Lewis and C. Ponnamperuma cover various aspects of chemical synthesis in the Miller-Urey vein. The biological

There are more than two hundred problems on a great variety of applications, distributed in clumps in mid-chapter as well as at the ends of chapters. Answers are provided to all the problems.

Although most departments will not wish to telescope courses together in the way Shercliff has done, the book should be generally useful as an additional text. Weak students will benefit from the wealth of applications for each abstract idea. Stronger students may be led on to read and understand material which a more formal textbook would leave out.

David J. Miller

David J. Miller is Lecturer in the Department of Physics and Astronomy at University College, London, UK.

papers (R. D. MacElroy, D. J. Kushner, R. L. Dimmick and M. R. Chatigny, R. S. Hanson and N. H. Horowitz) centre on the adaptability of microorganisms and their ability to survive in harsh environments having a variety of temperatures, pH, salt content, and even in aerosols. The energy requirements of a biosphere in terms of light input are considered separately by B. Kok and R. Radmer. Two essentially technique papers by E. E. Russel and M. G. Tomasko, and R. A. Hanel cover spin-scan imaging and infrared spectroscopy, respectively. NASA philosophy towards further planetary exploration is put forward by D. H. Herman and S. J. Grivas. Because of funding constraints rather than through any fault of the authors, the treatment is of a very general nature. A more important philosophical question raised by R. S. Young and R. D. MacElroy, concerns policy with respect to the possible irreversible contamination of any planetary surface or atmosphere, by organisms or molecules, carried on unsterilised or uncleaned space probes.

All in all, I feel this is a very useful book. Not, perhaps, of great value to the specialist chemist or biologist, but eminently readable by anyone with fringe knowledge of a variety of subjects and interested in studies on the origin of life. It provides many appropriate references and has a full index. As the object of the colloquium was to provide a forum for discussion, I wish an edited version of the question and answer sessions could have been included at the end of each chapter.

C. T. Pillinger

C. T. Pillinger, of the Department of Mineralogy and Petrology, University of Cambridge, UK, is a principal investigator in NASA's lunar sample analysis program.

obituary

Benjamin Lee

PROFESSOR BENJAMIN W. LEE died in an automobile accident on 16 June 1977. Director of Theoretical Physics at Fermi National Accelerator Laboratory and Professor of Physics at the University of Chicago Enrico Fermi Institute, Ben Lee was at the age of 42 deeply engaged in scientific activity at the forefront of high energy physics.

Born in Seoul, Korea, Ben Lee emigrated to the United States in 1956 and obtained citizenship in 1968. He studied at Miami University (Oxford, Ohio), the University of Pittsburgh and the University of Pennsylvania, where he was awarded a doctorate in 1960. His earliest work dealt primarily with dispersion relations and related techniques in the analysis of strong interaction phenomena, but he also had an early interest in Lagrangian symmetries and spontaneous symmetry breakdown, which ultimately became the focal points of his research.

By 1964 Ben Lee was a leading contributor to the study of the transformation properties of weak interactions with respect to strong interaction symmetries, and the intimately related question of the full symmetry properties of the strong interactions themselves. Through such studies the relevance of a spontaneously broken chiral symmetry gradually became apparent, and Lee contributed significantly to the construction and study of Lagrangian field theories which realise this property. His work demonstrating the renormalisability of these theories provided an encouraging model for later developments which led in 1971 to the establishment of renormalisability of spontaneously broken gauge theories. Following this breakthrough, Lee's work on the formal demonstration of renormalisability of gauge theories and on the elaboration of calculation techniques was of major importance in the further development of this field which has taken a dominant position in our present thinking.

As soon as the relevance of gauge theories for weak interactions began to appear highly probable, Ben Lee turned to the study of their practical implications, both for the newly discovered neutral current interactions and for the previously established properties of charged current interactions.

The use of new theoretical developments allowed a confrontation with experiment which placed severe restrictions on the possible choice of gauge models. It became increasingly clear that a viable model should incorporate charmed particles which had been postulated before achievements in renormalisation made such an inference compelling. Lee devoted considerable study to the expected properties of these particles and the possibilities for their experimental detection.

Along with the experimental discovery of charm, there has been a continuous experimental and theoretical evolution in the field of both weak and strong gauge theories, in which Ben Lee continued to participate fully. His rare combination of a familiarity with formal mathematical techniques and a close touch with experimenters and experimental results kept him at the forefront of many different aspects of these developments. At the same time he continued to reflect on the outstanding problems related to his earlier work on weak interaction symmetries and was quick to apply new developments to the clarification of old problems. He encouraged precision experiments designed to resolve long-standing questions as well as pioneering experimentation on the new phenomena.

Ben Lee's decision to remain permanently as head of the Fermilab theory group was not an easy one for him. He felt that at a university he would be freer to pursue fundamental theoretical questions. Yet while continuing to participate in the fast pace of theoretical research, he took extremely seriously the responsibilities of his position at Fermilab. On the one hand he attracted theoretical physicists of the highest quality as visitors to the laboratory and was in the process of putting together a small but strong nucleus of resident theorists. On the other hand he was deeply involved in laboratory policy concerning its present and future experimental programme, a job which he undertook with singular conscientiousness, endeavouring to learn the fine points of experimental techniques.

Before joining the Fermilab staff in 1973, Benjamin Lee was Professor of Physics at the State University of New York at Stony Brook. In addition to his responsibilities at Fermilab he served on the scientific policy com-

mittees for several major laboratories. He was the recipient of a number of prestigious scientific fellowships and had held appointments at many institutions in the United States and abroad. Perhaps his most meaningful experience in recent years was a visit to his native Korea where he was struck by the developing prospects for scientific research and found himself "working six days a week on upgrading graduate education in basic sciences" at the Seoul National University.

Ben Lee shared a close family life with his wife Marianne and teen-aged son and daughter at their home in Glen Ellyn, Illinois. Whenever possible they combined business with pleasure on trips to Aspen in Colorado, Europe and the Far East. An immeasurable personal tragedy for his family, Benjamin Lee's untimely death is a deep loss for the entire high energy physics community.

Mary K. Gaillard

Fred Hardy

PROFESSOR FRED HARDY, CBE, who died at St Augustine, Trinidad, in May at the age of 88 was the doyen of British tropical soil scientists. During his professional life the study of the soil developed from a subject that had little impact on practical agriculture to a discipline that has made major contributions to agricultural development, and Professor Hardy played a notable role in this transformation for tropical soil studies.

Almost his whole adult life was spent in the West Indies and Central America. His first appointment after leaving Cambridge University, was as lecturer in natural and agricultural sciences at Harrison College, Barbados, in 1911. He returned to England in 1917 towards the end of the First World War, then after the war spent a year at the School of Agriculture at Cambridge and then went back in 1920 to the West Indies as soil chemist with the Imperial Department of Agriculture, which was centred at St Augustine. This later became the Imperial College of Tropical Agriculture, and he became its first Professor of Chemistry and Soil Science. After his retirement in 1956 he served as Professor of Soil Science in the Inter-American Institute of Agricultural Sciences at Turrialba, Costa

Rica, for nine years before finally retiring to Trinidad.

Hardy's research career began after his return to the West Indies in 1920. He began by being interested in problems of soil water and the effect of water on some soil properties; then in the 1930s he became interested in the characteristics and genesis of tropical soils and laterites; and finally in the 1940s and 1950s he developed his well known studies on the soil factors that affect the fertility of tropical soils and their suitability for specific crops. In addition he was one of the early British soil scientists who realised the need for appropriate soil surveys for agricultural development, and I believe the first in the colonial Empire to institute a systematic soil survey, and he succeeded obtaining funds over a period of years for a survey of most of the British West Indies.

Professor Hardy had, however, a far greater influence on British colonial agriculture than would be judged from his research work, for almost every recruit to the Colonial Agricultural Service since the mid-1920s spent a year in Trinidad and most would study soils under him. His enthusiasm, his great friendliness and approachability, and his gift for picking out the most important points in any discussion, all left their mark; and his appreciation of the relation of the soil and the crop to the natural landscape must have influenced the ecological approach to agricultural development shown by many outstanding colonial agricultural officers.

E. W. Russell

William Parker

THE sudden and untimely death of William Parker, Professor of Chemistry at the University of Stirling, at his home in Dunblane on May 9 at the age of 45, has left the world-wide chemistry community with an immense feeling of loss.

Born in Glasgow in 1932, Willie Parker was a distinguished pupil of Whitehill Secondary School after which he went to the University of Glasgow where he took a first class honours degree in Chemistry in 1953. He started his PhD studies in Glasgow with Professor R. A. Raphael and completed them at the Queen's University of Belfast when Raphael moved there to his first professorial post. In 1956 Willie joined Professor G. Stork's group at Columbia University and then returned to the University of Glasgow where he rapidly moved up the academic ladder, culminating in his appointment to a senior lectureship in 1966. Promotion to readership saw him back in Ireland in 1968 at the

New University of Ulster where he spent two happy years helping to build up the new chemistry department there with characteristic drive and enthusiasm under the leadership of Professor M. Grundon. Armed with this valuable experience he returned to Scotland in 1970 to take up the first chair in organic chemistry at the University of Stirling.

Natural products, particularly the sesquiterpenes, were Willie's first love and in this area he published many important papers relating to their synthesis, biogenesis and rearrangements. In particular, he and his co-workers unravelled many of the problems associated with the molecular acrobatics of caryophyllene and humulene and their derivatives. Although he maintained this interest throughout his research career, a sabbatical year with Professor J. Berson at the University of Wisconsin in 1965 served to promote and nurture his growing interest in organic reaction mechanisms with particular emphasis on the solvolytic behaviour and preferred conformation of a wide range of bridged bicyclic compounds. Of particular note were his contributions to the understanding of the reactivity of bicyclo[3,3,1]nonane, bicyclo[3,3,2]decane and bicyclo[3,3,3]undecane (manxane) derivatives. At the other end of the spectrum he also had a keen research interest in the chemical factors influencing germination and dormancy in wild oat seeds. Shortly before his death, his group, together with collaborators in other disciplines, had made significant advances in this area.

Over the past eighteen years I knew him in many different rôles; as a teacher, as a research supervisor, as a colleague, as an opponent on the squash court and, above all, as a friend. In all these aspects his boundless enthusiasm, inexhaustible drive, unadulterated Glasgow humour, and extrovert personality made a tremendous impact on me as they did on so many other people. If ever there was a teacher who practised the subtle art of instilling a sense of dedication and professionalism in his students there was no greater practitioner than Willie Parker. Under his guidance and tuition organic chemistry came across as an exciting and challenging field of study.

Over the years many students, of whom I was one, continued their studies with Willie as their PhD supervisor. He shared in our triumphs and disappointments at the bench, our laughter and our tears. All of us greatly benefited from that experience and I have no doubt that his guiding principles and aspirations had a profound influence on us.

His rumbustious character came

through vividly in all the many facets of his work at the University. Willie was by no means an isolationist in an ivory tower; he enjoyed all his teaching commitments whether in the first year undergraduate laboratory with his sleeves rolled up or at the Monday evening postgraduate seminars. He approached his administrative duties both in the chemistry department and in the many university committees on which he served with a refreshing, down-to-earth attitude.

More than anything else he wanted to and did put the Chemistry Department of Stirling University on the map. I believe that he achieved this not only by his own personal reputation in the world of organic chemistry and by his service on national committees such as the Chemistry Panel of the Science Research Council, but also by his active encouragement of other members of staff to apply for grants and to seek and establish links with the chemical industry. Above all he had the unique ability to muster and channel our individual energies towards the common cause of creating a resourceful and stimulating department. His door was always open to those seeking advice and counsel. It is not surprising that he achieved so much during his relatively short trip to India last year while acting as project co-ordinator for a UNDP/UNESCO programme 'Special Assistance to Selected Science Departments in Indian Universities.' The United Nations could not have picked a better man for such a stamina-sapping mission.

Willie's tough professionalism really knew no boundaries; it overflowed onto many other areas including the sports field. His light blue tracksuit is a legend at Stirling University. Even beyond the campus his zest and vigour were manifest. At various times he was chairman of the local gardening club, a member of the male voice choir, and a coach to one of the Cub football teams. Just as Willie knew how to advise and encourage young academics, so too did he help the nine-year-old footballer. From his own student days as a keen footballer he remembered the importance of a new strip and the morale-boosting sing-song in the car returning from a 26-nil defeat.

All his many friends, both in the UK and abroad, have shared in one unique privilege—that of knowing the truly remarkable character of Willie Parker. For all of us, we are the beneficiaries of that enriching and rewarding experience, the memory of which will live on to compensate in part for our tragic loss which we share with his wife and three children.

James S. Roberts

When science turns up the unpalatable

THE Presidential Address of Sir Andrew Huxley to the British Association for the Advancement of Science, meeting in Aston, has been hyperbolically described in the press as "the first shot in what could become one of the most crucial and vitriolic scientific battles of the century". It certainly is an unusual, even courageous address.

His line of arguing is this. He asserts that "Science as a whole—the scientific approach to questions of all kinds—has come increasingly under attack . . . it is repeatedly suggested that the speed of scientific discovery should be slowed, and that scientists ought to suppress discoveries that seem capable of being used to the detriment of humanity". In a lengthy aside, he then acknowledges that scientists themselves often rely too much on grand unifying principles which inhibit their collection of evidence. But in a broader context too the collection of scientific evidence may be inhibited if it seems likely to touch on some particularly sensitive nerve in ordinary human affairs. Resistance, he claims, may be based on "Authority" or on the fear of the consequences of accepting the conclusion. Not for nothing does a Huxley hark back to the 1860s and the debate on this very matter occasioned by the publication of *Origin of Species*.

He asks if any topic stirs similar emotions these days. And he sees many features in common between the evolution debate of the last century and the current debate on the extent to which human ability is inherited, although he points out that the analogy would be better had Darwin gone public twenty years earlier when his case would have been weaker, but certainly not hopeless. The resistance these days to research in the field of the heritability of human ability comes from a feeling that our ethics may be undermined because the existence of substantial inherited differences would lead to unjust treatment of the less-well endowed, and that discoveries of below average ability would damage self-respect.

More sinister than anything in the evolution controversy, says Sir Andrew, is that there are actually scientists who regard the assumption of equal inherited ability as "something which does not require experimental evidence to establish it and which it is positively wicked to question because the conclusion might disagree

with their social and political preconceptions". Thus when someone (William Shockley) had the "courage to suggest systematic and scientific investigation" he was repeatedly turned down by the National Academy of Science. Sir Andrew accepts that at the time Shockley was advocating eugenic measures unacceptable to public opinion, but thinks the main reason for refusals was fear that it would be represented as a "commitment to an illiberal point of view unfavourable to American Negroes". He feels that such behaviour is an unjustifiable obstacle to human enquiry and impedes or distorts the advance of science.

Freedom for scientists to investigate whatever they want may be a valid rallying point in some circumstances and under some tyrannies. But scientists are already under some external constraints on their freedom, for ethical and financial reasons, and it is clearly not possible simply to say that everything that is observable and measurable ought, in the name of science, to be observed and measured. The question then revolves around the motives for doing research into heritability. There are, of course, two extremes—those who believe that the world should know that the less well-endowed are going to stay that way and those who believe that the whole thing is both scientifically unsound and an affront to certain people, and should be stopped forthwith.

Is there middle ground? If there is, and many intelligent and thoughtful geneticists believe there is, it needs staking out with immense care. Those who propose that research be stopped have some very human motives behind them, and it is no answer simply to wave freedom of scientific enquiry in their faces. Questions are bound to be asked about motives for doing more research, especially as there is little doubt that inheritance does play at least some and maybe a very significant part in the acquisition of ability. Some who want to do more only want to do so to rub in assumed inferiorities. What Sir Andrew should have done is take his argument further and set forth reasons why more research at this time, with its close proximity to sensitive issues, is desirable. Such a case can probably be made out but it would need a rather more spirited explanation of why we are better off with the knowledge than without it. □

La Soufrière, volcanology and forecasting

Last year Haroun Tazieff, of the Laboratoire de Volcanologie, Centre de Faibles Radioactivités, Gif-sur-Yvette, France, had to leave his post as director of the Service Volcanologique at the Institute of Physics of the Globe over the eruption of La Soufrière. Below, his account of the problems

IN THE past six years at least four erroneous volcanological diagnoses, based either on wrong interpretations of actual facts or on deliberately false data, have induced governmental authorities in four countries to take unnecessary and expensive measures. Together they show that volcanologists may sometimes be confronted with quite serious socio-economic consequences of their own forecasts.

● The first case was in 1970 in Italy's Neapolitan area. A submarine eruption was claimed to have burst out offshore of the city of Pozzuoli, approximately 2 km west of the well-known Solfatara fumarolic field. After the mass-media told of possible explosions, ash-falls and sea-waves, the Army and the *carabinieri* (police) helped the frightened population to evacuate the city. The claimed symptoms were an upheaval of the ground in the whole area, which had been pushed up about one metre in a "very short while"; extremely shallow earthquakes, located 1 to 2 km offshore; a conspicuous temperature-rise of the Solfatara's fumaroles; and the outflow of hot fluids on the bay's floor, inferred from dead boiled fish fishermen took in their nets.

The last three items were subsequently proved totally false by a team of six scientists led by myself, and I disclosed the fact at a press conference. On the other hand, the upheaval, the so-called brady-seism of Pozzuoli, had not been faster than usually noticed over the centuries during which up-and-down level variations of that peculiar area had been classically observed. Eventually it was stated that deliberately wrong data had been produced by the scientist in charge of the geophysical institute of Naples. This was connected to a construction operation in which high-rank people were involved. The evacuation of the inhabitants was proved to be expensive and useless.

● The second case happened during the 1972 eruption of St Vincent's Soufrière in the West Indies. Notwithstanding the clearly expressed and reassuring opinion of Dr J. Tomblin, the volcanologist in charge, an alarming cable from a scientist some thousand kilometres away was taken into consideration. This 'televolcanologist' had deduced his frightening conclusions from earth-satellite imagery and the whole population was consequently moved away. Here too it proved both expensive and useless.

● The third case happened in 1973 during the last days of the Heimaey eruption. Persuaded by a somewhat inexperienced foreign volcanologist, Icelandic authorities agreed to use fire-boats to sprinkle water on a tongue of the thick lava flows which over several weeks had progressed at a distressing speed towards the harbour entrance. No arguments could prevent the exercise: not even the evidence that the Atlantic ocean itself, with all its water, had not been able to stop the main part of the flows which had crawled over the sea-floor for two months.

● The fourth error occurred in 1976 during the eruption of La Soufrière in Guadelope in the West Indies. Here too, in spite of the firm statement of the volcanologist in charge that no danger lay ahead, the authorities followed the alarmist opinion expressed first by a petrographer and then

by a geochemist, both of whom lacked experience of eruptive phenomena. Consequently 73,600 people were evacuated on 16 August and were kept away from their homes and jobs for 3½ months. It proved very expensive, dramatic for the population, and totally useless.

A volcanologist is actually as responsible for his diagnoses as is a physician—even more so, because of the number of people involved and because the costs are usually far bigger. This implies that some sort of deontological code, similar to the medical one, should exist for practising volcanologists, and that illegal practice should be prohibited in this field just as it is for medicine. Whatever their field, scientists cannot remain detached from the eventual effects of their work on the everyday life of other people.

The easiest course for the authorities is naturally to choose, amongst various scientific counsels, the most pessimistic if not necessarily the best one. Their responsibility is then shielded against the worst, and if the catastrophe eventually does not occur the only reproaches they suffer are minor ones that are swiftly forgotten. To express a volcanological forecast is always an awkward business. Like civil administrators, many a volcanologist will naturally tend to be pessimistic rather than optimistic, if only to avoid exposing people to some danger he would have disregarded; he would want to avoid being accused if his own optimistic forecast proved unfounded. Though understandable enough, such an attitude is not in accord with the deontology code; a deliberately pessimistic physician is not necessarily considered a good medical doctor.

But some points seem clear. First of all, no volcanologist should state any opinion if his knowledge of eruptive phenomena is below a minimum level. Secondly, the consultant volcanologist should express his scientific opinion without altering it in either an optimistic or pessimistic way. An honest volcanologist, whatever his experience, all too frequently will not be able to describe much more than his incapacity to tell what will follow next. Nevertheless, a valuable forecast is sometimes possible and our own experience shows examples of it.

It actually happened in 1976 at the Guadelope Soufrière, when a rather unusually flat and valid conclusion seemed evident to any experienced volcanologist: absolutely no risk existed that the volcanic event which the whole Caribbean population most feared—*nuées ardentes* (glowing avalanches) of the Mt Pelée type—could happen at all in the near future. I delivered this view, while several other scientists claimed the opposite. But it was obvious that the eruptive events, which were started during the autumn of 1975 by a volcano-seismic crisis, had then passed to phreatic kinds of outbursts in which no fresh magma at all was involved, and would not develop into *nuées ardentes*. The French government nevertheless chose not to listen to this plain argument, asked geologists unskilled in volcanology and proceeded to evacuate the entire population of 73,600 people. The whole issue developed in phases.

● The seismic activity of the volcano started in October 1975 when the seismographic array of the Soufrière Observatory began recording swarms of microearthquakes. For several months, these swarms increased in both number and intensity; the first felt earthquake occurred in late March 1976. At this point several scientists expressed anxiety, more because of the high number of recorded microearthquakes than because of their actual energy. None amongst them had any experience in eruptive phenomena.

The opposite opinion was based upon the two following facts. First, far more frightening volcano-seismic crises had previously been observed in the Caribbean, and many more

still in Japan, where the most earnest attempts in the world have been made in volcanological forecasting. At the Omuro volcano in 1930, for example, 4,880 shocks located between 2–7 km below the surface were recorded in less than three months; at the Hakone volcano in 1959–60, the foci of the recorded earthquakes were located 0.8–5 km below the surface, but on the basis of the complete lack of any B-type earthquake shallower than 0.8, Minamaki predicted that no volcanic eruption would happen and he was right. In the Carribean, two volcano-seismic crises occurred at Montserrat island in 1897–98 and 1933–36, and are well known to volcanologists; neither of these well-studied crises finished with volcanic eruption. It therefore made sense not to be unduly alarmed by the 1976 seismic events of the Soufrière.

Secondly, the focal depths of the earthquakes during the Soufrière crisis were located at 2–6 km, depths quite similar to those which had characterised the Hakone and the Omuro crises. This meant that many months, or more probably years, should be necessary for the Soufrière viscous magma to reach the surface, for any magma is supposed to be far slower than its own lavas, and all the Soufrière lavas had obviously been comparatively viscous and slow. Experience has shown that most frequently the average speed of lava flows of the same kind as those of the Soufrière varies between less than 1 and about 100 cm h⁻¹. From a spot located below 6 km down, the corresponding feeding magma should therefore require several years to reach the surface. If any factors had been overlooked, or if the magma velocity would drastically increase, several months seemed a minimum for it actually to become eruptive. Consequently one could quite confidently speak of a period of several weeks, at least, before the start of any magmatic event.

To the objection that a body of molten (and therefore not seismic) magma could be stored *above* the uppermost foci, that is, between the surface and the 2 km depth—meaning that a hypothetical reservoir was located within the 1,400 m thick volcanic heap itself—the answer was that both the temperatures measured close by in the geothermal field of Bouillante (70 °C near the surface and 240 °C 350 m down) and the gas composition of the Soufrière fumaroles (in vol % : CO₂, 90–93%; H₂S, 0.6–1%; CH₄, 0.5%; H₂, 0.5–1.2%) proved such a hypothesis to be quite improbable.

● On 8 July 1976 the eruption started its second, actually eruptive, phase when so-called ‘ash’ outbursts were superimposed on the almost continuously increasing volcano-seismic activity. This second phase lasted eight months, during which 20 phreatic eruptions occurred, the last one on 1 March 1977. Each outburst lasted only a few minutes (less than 20) and expelled steam and water droplets mixed with some volcanic gases laden with ejecta. These ejecta, ‘ashes’, sands and blocks, were exclusively composed of old rock material, with no trace of any fresh magmatic material. The first of these phreatic eruptions started noiselessly and propelled a dark mushroom hundreds of metres above the top of the mountain. This plume was then driven south-westwards by the wind. From the volcano windwards, the sky became totally dark, and a thick rain of small lapilli and dust started, which lasted for about 20 minutes. Several thousand people fled as soon as the darkness cleared up.

The scientists called by the authorities were divided. Some of them felt afraid, firstly because they feared that these ‘ash explosions’ could lead either to *nuées ardentes* or to mud-flows, or both. The opposite opinion was that these risks did not exist because this eruption obviously belonged to the phreatic kind: gas analyses, measured steam temperatures, as well as examination of ejecta showed that no fresh hot magma or lava were involved and that, consequently, no *nuées ardentes* could be expected. On the other hand, as in phreatic eruptions, the

very first outburst usually is the strongest one, and as the 8 July one had generated only a small mud-flow, it was to be supposed that further lava hazards would be minor. In spite of an apparent tendency to prefer pessimistic diagnosis to reassuring ones, the government authorities were consequently prevented from evacuating people.

The second phreatic outburst occurred on 24 July. Asked by the *prefet* and having obtained the data from and opinion of my collaborators, now permanently monitoring the fluid and solid exhalation of the volcano, I concluded that there was no more danger ahead than two weeks before.

● The third outburst happened on 9 August. I was in the Ecuadorian Andes involved in a volcanological expedition with two of my collaborators, but our three colleagues were still on La Soufrière, mainly to monitor the chemical and physical evolution of the gas phase, which may be considered as a good indicator of the eruptive evolution itself. These skilled volcanologists declared that no threatening change was to be feared in the eruptive events. This was because of the following facts: first, the gas composition had not changed. The proportion of CO to CO₂ was about 10⁻³–10⁻⁴, and of H₂S to SO₂ was about 10; in addition, the focal depth of the earthquake had not moved, no trace of any magmatic activity was detectable anywhere, either in the erupting area or on the lower slopes of the volcano, and old rocky material *exclusively* was to be found around the eruptive vents.

Disregarding these volcanologists’ opinions, the civil authorities nevertheless called from France two geologists without any experience in the field of eruptive activity. The first decided to have the whole population immediately evacuated; the second decided to enforce the precautions and maintain them for several months on.

Their diagnoses were based, first, on the assumption that the seismo-volcanic crisis—up to 1,257 shocks, half a dozen of which had been slightly felt, in one day—had reached such a climax that nothing but a catastrophe could proceed, and secondly on the claimed presence of fresh volcanic glass in the erupted ‘ashes’, the meaning of which was the imminence of *nuées ardentes*. Professor C. Allègre, on 5 September 1976, produced an official report in which he stated that 50–60% of fresh volcanic glass was present in the erupted ash. He was later compelled to admit that actually no trace of fresh material had ever been detected.

According to *Le Guern* (in press) the twenty outbursts which occurred between the first (8 July 1976) and the last one (1 March 1977), as well as the more or less continuous emission observed at the active vents throughout the same period, have poured out a total output of the order of 6–10 × 10⁶ tons of steam and 1.5–2 × 10⁶ tons of ‘ashes’ and blocks. According to the same author, a surface less than 1 km long and 300 m wide received a total ‘ash’ fall 300 m thick for the whole nine-months-long event. The closest town, Matouba, some 3.5 km west (windwards) from the craters, got a total ‘ash’ fall of 5–15 mm according to the spots. The closest city, St-Claude, 4.5 km west-south-west from the erupting vents, got a total 2–5 mm thickness of ‘ash’. The longest mud-flow, which resulted from the first rain eastwards over less than 3 km.

These figures show how modest was the scale of this eruption. The above mentioned criteria and their interpretation explain how our so-called ‘optimistic’ diagnosis had been attained. The main lesson of this unfortunate experience is perhaps to confirm the absolute necessity for a good volcanological interpretation of all the available, geological, geophysical, chemical and phenomenological data before expressing any forecast. Volcanologists, just as medical doctors, should be responsible, skilled, experienced, different specialists closely co-operating with each other. And they should keep as cool as a cucumber. □

Voyage to the outer planets

Both NASA's Voyager spacecraft are heading for the outer planets. **Stuart Sharrock** describes the journey they will make

WHEN the outer planets were last aligned so that a spacecraft could visit each in turn on a single voyage, Thomas Jefferson was President of the United States. Understandably none took advantage of that opportunity. But in the 1980's, the opportunity to fly past each outer planet will occur again and if it is not seized then it will be lost for several generations.

NASA's original plan to take advantage of the 1980's alignment consisted of sending two spacecraft on a visit to every planet from Jupiter to Pluto. Nicknamed the 'Grand Tour', that project soon fell victim to budget cuts and the current Voyager mission was developed as something of a consolation prize. The Voyager mission, however, is itself ambitious enough. Its two spacecraft, launched on 20 August and 5 September, are intended to scrutinise Jupiter, Saturn and their moons, with an option for one to continue to Uranus and Neptune.

A mission to the outer planets is a radically new adventure. The inner planets, Mercury, Venus, Earth and Mars are rocky worlds which have been intensively studied. They seem to bear little resemblance to the gaseous outer planets that dominate the solar system. But very little is known about Jupiter and Saturn and next to nothing about Uranus and Neptune. Only two spacecraft have ever reported from the region beyond Mars; Pioneers 10 and 11 flew past Jupiter and returned intriguing but inconclusive data. Pioneer 11 is expected to reach Saturn in 1979.

The two Voyager spacecraft will reach Jupiter in 1979. More massive than all the other planets put together, Jupiter is an enormous ball of gas at the centre of a miniature solar system of its own. Four of its thirteen known moons are as large as some planets and Voyager will take a close look at five of them, concentrating on Io with its associated strong concentration of charged particles which appear to modulate the powerful radio bursts from Jupiter itself.

By visiting Jupiter, Voyager will be able to halve the journey time to Saturn. It will take advantage of the increase in velocity provided by Jupiter's gravitational field and should make the flight to Saturn in just over three years instead of the normal six. This 'gravitational assist' technique may be used again at Saturn to sling one of the spacecraft to a rendezvous with distant Uranus in 1986.

The spectacular rings around Saturn will be only one object for investigation. Like Jupiter, Saturn emits more energy than it receives and it has an extensive system of moons. Voyager will visit seven of the ten moons and will take particular interest in Titan, a moon larger than the planet Mercury and with an atmosphere. Titan is thought to be a far better place than Mars to search for evidence of extra-terrestrial life; the theory that life on Earth developed from a primitive reducing atmosphere implies early conditions on Earth similar to those which now exist on Titan.

Jupiter, Saturn and Titan are the prime objectives of the mission. If the first spacecraft, Voyager 1—which takes a faster route to Jupiter and was therefore the second to be launched—fails to complete its investigation of Titan, Voyager 2 will be redirected to do the job again. Only if Voyager 1 is successful will Voyager 2 fly directly towards Uranus and eventually, after a 13-year flight, to Neptune.

Special design features

Even if the mission does not extend beyond Saturn, its lifetime will be long and the distance travelled vast compared to previous missions. To cope with these conditions, the Voyager spacecraft require special design features. The familiar arrays of solar panels are missing as the energy received from the Sun as far away as Jupiter is only 4% of that at the Earth; at Saturn it is down to 1% and at Neptune 0.1%. Instead, radioisotope thermoelectric generators, which should last the journey to Neptune,

supply power to the spacecraft. The power requirements are great because signals have to be sent across such large distances. The spacecraft will be the first to communicate via the high frequency X-band channel, allowing high data rates which are essential at various stages of the mission.

The 11 instruments on board include television cameras, infrared and ultra-violet spectrometers, charged particle detectors, magnetometer and plasma wave detectors and, for the first time on an interplanetary probe, radio wave detectors. All experiments have to operate at liquid nitrogen temperatures and because of the length and complexity of the mission almost everything that could fail has a back-up system—including the two spacecraft themselves which are identical.

With such a complex mission the chance of something going wrong is high, but Voyager has already had more than its fair share of troubles. Very near 20 August, the launch date of the first spacecraft (designated Voyager 2), computer problems were discovered. A rapid switch of the two spacecraft meant that Voyager 2 could be launched on time and that Voyager 1 which was due for launch on 1 September would be delayed by a few days. But the first launch was rough. Computer failure occurred again, there were apparent problems with gyroscopic stabilisation and the boom containing the television cameras did not deploy fully. There were even speculations that the spacecraft had been struck by its own discarded rocket engine. The problems were overcome but inevitably the mission has already been compared with Mariner 10 which had to be nursed continually during its 17 month trip to Venus. The outlook for Voyager 1, though, is brighter. According to NASA it went up on schedule and with no hitches on 5 September. □

Voyager mission highlights

Date	Event	Range (km)	Resolution (km)	Spacecraft
20 August, 1977	Launch			Voyager 2
5 September, 1977	Launch			Voyager 1
15 December, 1978	Start Jupiter imaging	80×10^6	1.5×10^3	Voyager 1
5 March, 1979	Closest approach Jupiter	278×10^3	6	
5 March, 1979	Io	22×10^3	0.5	
April, 1979	Conclude Jupiter imaging			
20 April, 1979	Start Jupiter imaging	75×10^6	1.5×10^3	Voyager 2
10 July 1979	Closest approach Jupiter	643×10^3	13	
August, 1979	Conclude Jupiter imaging			
August, 1980	Start Saturn imaging	100×10^6	2×10^3	Voyager 1
11 November, 1980	Titan	4×10^3	0.5	
12 November, 1980	Closest approach Saturn	138×10^3	3	
January, 1981	Conclude Saturn imaging			
June, 1981	Start Saturn imaging	100×10^6	2×10^3	Voyager 2 (assuming Voyager 1 successful at Titan)
27 August, 1981	Closest approach Saturn	102×10^3	2	
27 August, 1981	Edge Saturn rings	38×10^3	0.8	
October, 1981	Conclude Saturn imaging			
January, 1986	Uranus encounter			
September, 1989	Neptune encounter			

USA

Action on antibiotics

Colin Norman reports from Washington on the Food and Drug Administration's (FDA) recent action to ban the use of some antibiotics in animal feeds

AFTER more than a decade of controversy and several years of vacillation, the Food and Drug Administration (FDA) last week took the first formal step towards removing antibiotics from animal feeds, a step long urged by some scientists but bitterly resisted by the agricultural and pharmaceutical industries. The FDA issued a regulation which, provided it survives an expected slew of legal challenges, would prohibit the addition of small amounts of penicillin to premixed feeds for pigs and poultry. A similar regulation banning tetracyclines will follow soon, FDA announced.

Antibiotics have been added to animal feeds in the United States for 25 years, following a discovery that they help promote growth and hence shorten the road to the slaughterhouse. The practice has become so common that, according to figures collected by FDA, some 48.6% of all antibiotics produced in 1975 were added to animal feeds. In the mid-1960's, however, some scientists began to warn that such widespread use of antibiotics may be contributing to the growing problem of antibiotic resistance among microbes which cause human and animal diseases—resistance which is seriously compromising therapeutic uses of some drugs.

One concern is that bacteria which cause disease in animals will become resistant to antibiotics, thus making the disease more difficult to treat. Another concern is that the resistant bacteria may be transferred from animals to humans either directly or through meat, milk or eggs. An added dimension to the concern is the fact, which is now widely established, that antibiotic resistance can be passed from one strain of bacteria to another—for example, an animal bacterium which becomes resistant to an antibiotic may pass its resistance to a human pathogen through a chance encounter. (Antibiotic resistance is largely determined by so-called R-plasmids, tiny rings of DNA which sit inside a bacterial cell and are reproduced each time the bacterium divides).

Those concerns led the British government in 1968 to establish a special committee, under the chairmanship of Professor Sir Michael Swann,

to review the problem. The Swann Committee concluded "the administration of antibiotics to farm livestock, particularly at the sub-therapeutic levels, poses certain hazards to human and animal health", and it recommended a ban on the routine addition to animal feeds of antibiotics used to treat human and animal diseases. The British government swiftly adopted the recommendation, and other European governments have since followed suit.

Following publication of the Swann Report, FDA established a task force of its own to look into the matter, and in February 1972, the task force recommended that restrictions similar to those adopted in Britain should be imposed in the United States. But the task force put an important proviso on that recommendation: the ban should be delayed for up to two years to allow the drug industry time to try to prove its claim that the use of antibiotics in animal feeds does not lead to human health hazards. The deadline slipped by, but FDA took no formal action and non-therapeutic drug use on the farm has continued to increase. According to FDA estimates, 1.2 million pounds of antibiotics were added to animal feeds in 1960, 7.3 million pounds in 1970, and an average of 7.7 million pounds each year between 1971–75.

The first public indication that FDA hadn't completely forgotten about the problem came last April when Donald Kennedy, the new FDA commissioner, announced that FDA was finally prepared to act. "Although we can point to no specific instance in which human disease is more difficult to treat because drug resistance has arisen from an animal source, it is likely that such problems have gone unnoticed", Kennedy said. "The benefit of using these drugs routinely as over the counter products to help animals grow faster or in prophylactic programs does not outweigh the potential risk posed to people", he added. Consequently, Kennedy announced that FDA would seek to eliminate use of penicillin and severely restrict use of tetracyclines in animal feeds. (It should be noted that some antibiotics most critically needed for therapeutic use in man and animals, such as chloramphenicol, semi-synthetic penicillin, gentamycin, and kanamycin, have never been allowed in animal feeds.)

Last week FDA formally published a regulation barring use of penicillin in animal feeds, (it is used chiefly for pigs and poultry), and a similar ban

Donald Kennedy: new commissioner

on tetracyclines is expected in the next few weeks. Other antibiotics are under consideration, but FDA officials say they do not expect to take action on them in the near future.

The FDA decision is sure to be controversial, and the agriculture and pharmaceutical industries are expected to challenge it in court. One reason is the economic impact. FDA reckons that eliminating penicillin alone will cost some \$12 million in lost sales and increase feed costs: the impact of eliminating tetracyclines is expected to be even higher.

The industry is expected to argue on several different grounds. First, there is no demonstrated case in which antibiotic resistance derived from lacing animal feeds has led to untreatable bacterial infection in humans. Second, that resistance to penicillin and tetracyclines is already so widespread that banning their use in animal feeds will make little difference. And third, the chief reason why antibiotic resistance has become such a serious medical problem is that antibiotics have been overused and inappropriately prescribed by the medical profession.

The industry has a right to appeal the FDA decision by filing a complaint and requesting a public hearing, a process which could take up to a year and use of the drugs in animal feeds would be permitted until the appeal is exhausted. After that, the industry could go to court in an attempt to overturn the ban.

Even if the FDA action is ultimately upheld, the use of antibiotics in animal feeds will not be ruled out entirely. The pharmaceutical industry has produced a number of antibiotics which are not used to treat human disease and which may therefore be safer replacements for penicillin and tetracyclines. According to FDA officials, those antibiotics are not in widespread use because they are more expensive than penicillin and tetracyclines. □

USSR

Discrediting the dissidents

Vera Rich reports on efforts within the Soviet Union to play down the strength of dissident opinion

THIS autumn, the Soviet Union will be celebrating the sixtieth anniversary of the October Revolution. Unlike previous anniversaries, this one will take place against a background of dissident opinion which, to the obvious embarrassment of the official concept of Marxist-Leninism as a 'scientific' basis for society, includes among the dissidents a number of scientists.

Accordingly, it would seem that there is a last-minute campaign to reduce the impact of the dissident movement on the outside world before the celebrations commence, by means of media propaganda.

A recent article in the prestigious *Literaturnaya Gazeta* attacked the Oxford conference on physical chemistry and hydrodynamics which was held in honour of the sixtieth birthday of Corresponding Academician Veniamin G. Levich. Totally ignoring the scientific work of the meeting (for which see *Nature* 268, 298-299, 28 July, 1977), the article set out to prove that the organisers, Sir Derek Barton and Professor Brian Spalding, had been little more than figure-heads for organisers

"far removed from science". It cited the fact that a few of the Soviet scientists invited were already dead. Professor Spalding said that he had found the names of the Soviet scientists in a 1976 edition of the *World of Learning* and added that a few clerical errors were inevitable in organising a large conference.

Commenting on the article's other main charge, that Professor Levich had long ceased to work in science, Professor Spalding pointed out that this was a particularly wicked accusation, since it was the Soviet authorities' harassment that hindered Levich from continuing his scientific work. Spalding further noted that the author of the article seems to have violated the secret archives of the Academy of Sciences, concerning Levich's failure to be elected full Academician. Since the Academy elections are still by secret ballot, this seems ominous.

Somewhat similar in tone were the numerous broadcasts (largely in western languages) which preceded the Honolulu Congress of the World Psychiatric Association (WPA). The message was simple: Soviet psychiatry is a purely therapeutic activity, and all suggestions of the psychiatric repression of dissidents are simply propaganda. A number of western psychiatrists were cited

as having concurred in the diagnoses given to alleged dissidents. However, Dr Avtandil Papiashviliar, a psychiatrist who recently emigrated to the West, said in London that such claims were "a straightforward lie". He further maintained that during the WPA Symposium in Tbilisi, in 1974, the KGB had arranged for a genuine mental patient to break into the meeting, claiming to be persecuted by the police, in the hope that the visiting delegates would first protest, and then have to admit that the man was indeed in need of psychiatric attention. In the event, the Honolulu Congress passed (albeit narrowly) a motion censuring Soviet psychiatric repression of dissidents and the Soviet delegation decided not to secede from the WPA.

Honolulu can rightly be claimed as a success for all those concerned with the human rights movement in the Soviet Union. No such success, however, can yet be claimed for the recent Anatolii Shcharanskii hearing in the Swedish House of Parliament. Shcharanskii, a young mathematician who was a founder member of the Moscow 'Helsinki Monitoring Group', was arrested last March accused of spying for the CIA. The Stockholm hearing, before Hårje Stenberg, Master of the Swedish Appeal Court, not only presented circumstantial evidence of Shcharanskii's innocence, but also pressed for his human right of a fair trial. □

NEW ZEALAND

●The latest budget from the New Zealand government gives a substantial fillip to the country's Department of Scientific and Industrial Research. Although the country is going through difficult economic times expenditure on science-related activity is to rise by 16% to \$NZ 35 million for the financial year 1977-78 (£1=\$NZ 1.78). That increase should keep pace with inflation and provide for some real increase as well but staff figures in the Department continue to be held at just over 2,000.

The budget allocation breaks down into \$NZ 14 million on agricultural work; \$NZ 3.15 million on energy; \$NZ 3.41 million on manufacturing; \$NZ 6.81 million on the natural environment; and the balance on miscellaneous activities. The department is making a special effort on energy research in efforts to discover long-term alternatives to New Zealand's reliance on overseas sources of fuel.

Meanwhile university research personnel gained some benefit from the budget, having gone through a very

lean time. Last year the Universities Research Fund was denied funds by the government in a savage attack on spending. This budget allocates the Fund \$NZ 750,000.

●A master file of over 14,000 earthquakes in earthquake-prone New Zealand has been established. The file has been placed on computer tape and runs from the first recorded earthquake in AD 1460 to the most recent shocks of 1975. The file will greatly assist the task of scientists working out the geographic patterns of earthquakes and researchers in the construction industry.

●A Royal Commission on Nuclear Power is sitting in New Zealand in an effort to discover the real needs of the country before any step is taken to set up nuclear power stations. The Labour opposition has been vigorously opposed to nuclear power but the Conservative government is waiting on the Commission. The Minister of Energy Resources, Mr George

Gair, says he believes the country has at least five years in hand before any decision need be taken.

●The government has set up a working party to examine the need for legislation to control genetic engineering experiments which are going on in New Zealand. So far, the few scientists working in the field have agreed to abide by the Williams Committee guidelines from the United Kingdom, but now the government believes further study is needed.

●Just to produce and supply electricity to New Zealand's three million people is calculated to cost about \$100 for every person. In an effort to recoup the costs the government continues to allow energy prices to rise. But in the search for alternative sources the government will control a major on-shore drilling programme, take over an off-shore mining company and the Natural Gas Corporation which controls the Maui gas field.

Bruce Wallace

IN BRIEF

Instant data

By 1979 experimental data should be travelling between four major European high energy physics laboratories almost as fast as it can be processed. Under a project called STELLA (Satellite Transmission Experiment Linking Laboratories), which will involve the UK's Rutherford Laboratory, DESY in Germany, Saclay in France and CERN in Geneva, the data will be transmitted via the Orbital Testing Satellite, the European Space Agency's communications satellite scheduled for launch on 8 September.

The project has recently won approval from the Council of Ministers of the European Economic Community for funding worth SF 1.2 million, which will be spent on building a small satellite earth station and associated computer at CERN. It should demonstrate to industry and Europe's posts and telecommunications organisations, the value of using the new design of

European satellite for transmitting data almost instantaneously at very low error rates.

Spacelab selection

Last week, 12 European countries put forward 53 candidates for selection as Europe's first astronaut. Whoever is chosen will travel with one American on the first mission of the European Space Agency's (ESA) Spacelab, a reusable space laboratory which will be put into earth orbit in 1980 by NASA's Space Shuttle.

By the end of this year the 53 candidates will have been whittled down to six who will undergo further tests by NASA and ESA. Before the middle of next year, three will have been chosen for intensive training for the first Spacelab mission. A few months before the launch, one will be finally selected to travel in Spacelab while the other two work on ground-based activities.

The UK has put forward five candi-

dates, the maximum number any member country of ESA was allowed to submit. They are William Grut from Surrey University, Geoffrey Firmin from Associated Nuclear Services Ltd, Arthur Ince from East Birmingham Hospital, Keith Mason from the Mul-lard Space Science Laboratory and M. J. Rycroft from Southampton University.

Whilst Europe has been selecting candidates for Spacelab, NASA has been working out how much to charge customers for flights on the Space Shuttle. The cheapest fare, at \$10,000, is likely to be for payloads involving research, weighing less than 200 pounds and with a volume less than five cubic feet. The maximum fare will be around \$21 million for full use of the Shuttle by non-US government customers. NASA already has 40 payloads for 1980, the first year of the Shuttle's operation. Spacelab is due to go up on Space Shuttle flight 11 for a fare somewhere in the middle of the price range.

AGRICULTURAL productivity throughout the world is increasingly dependent on the liberal use of chemical fertilisers, particularly those containing nitrogen. This is true of the sophisticated farming systems in Europe and North America, and where the 'green revolution' is successful in developing countries. A substantial amount of energy and oil goes to produce these fertilisers, and therefore many people are doubtful whether their continued and increasing use will be possible in an energy-hungry world in the twenty first century.

As I showed on 25 August, oil-hungry tractors actually use less energy than horses on the farm. Chemical fertilisers may, on balance, increase the amount of energy available to the farmer and to the population he serves. Returning to our Kalahari bushman, so idolised by some ecologists for his allegedly-economical use of energy; he certainly extracts many more calories than he puts into the system, but he only obtains enough food from a square mile or more of territory to feed himself. The modern arable farmer feeds several people on the produce of a single acre. He puts more into the system, but he takes a great deal more out. The difference between his energy expenditure, in cultivation, spraying and harvesting, and that stored in his crops, is several hundred times that of the bushman's total productivity per unit area.

In the UK we use less than a million

tons of oil to produce over a million tons of nitrogenous fertiliser. Only a part of this is used on cereal crops which now yield annually some fifteen million tons of grain and ten

Food for energy

KENNETH MELLANBY

or more million tons of straw. Without the fertiliser the yields would be reduced by a factor of two or even three. The energy wasted by burning some three million tons of unwanted wheat straw could, in theory, power all our tractors and the factories making our manures.

Unfortunately we cannot, at present, use the straw in this way, but we should surely try. To turn straw, readily available on the surface of the

ground, into useable fuel should be a simple problem for our research workers to solve. A fraction of the money used for more esoteric agricultural research would be well invested to this end.

Although arable farming uses energy efficiently, further improvement is desirable, if only to reduce costs. In Britain we waste a substantial amount of organic manure which would save synthetic chemicals and might improve soil structure, but which, when fuels are cheap, is expensive to use. As fuel prices rise, this waste will be avoided. Cultivation may be further reduced when weeds are controlled by modern herbicides. Though it will probably be a long time before research to make it possible for cereals to fix atmospheric nitrogen gives positive results, we now make too little use of the ability of leguminous crops to perform this function. World phosphate supplies are limited, but fungal mycorrhizae may be increasingly used to mobilise insoluble compounds in the soil. All the indications are that in future agriculture will use less and not more energy, without any loss in productivity.

Thus though we may face a global energy shortage in the next twenty five or thirty years, so that the extravagant use of cars and aeroplanes may have to be restricted, and we may have to stop overheating our houses and offices, we should, with a rational system of priorities, have plenty of energy to produce our food.

Alaskan earthquake

SIR,—The item on Alaskan earthquakes by P. J. Smith (7 July, page 12) is misleading—the point at issue is not the frequency of seismic events in Northern Alaska, but their magnitude.

The section of the pipeline of which he writes was required to be designed to withstand an earthquake of magnitude 5.5 without spillage; the federal requirements were only drawn up after extensive analysis by a variety of groups not depending solely on seismic data. Obviously these people appreciated that the absence of recorded activity was more apparent than real. I can see no reason to assert, as Smith does, that a report on the frequency of seismic events in the magnitude range 1 to 4 for a section designed to resist magnitude 5.5 shocks reveals an example of oversimplification through ignorance.

I might add that many crude oil pipelines around the world were built before good seismic data became available (for instance in Iran early in the century) and there is no record of any of them ever having ruptured as a result of an earthquake.

Yours faithfully,

F. G. LARMINIE

British Petroleum, London, UK

China and scientific unions

SIR,—In your editorial (28 July, page 283), you accuse The People's Republic of China of "trying to import" politics into the international scientific unions. You ignore the fact that politics must inevitably play a role in the unions as they are at present constituted. For example, how can a union, composed of member countries and financed by their governments, fail to consider the question of what is meant by a country?

In discussing Chinese representation in the unions one should remember that Taiwan has never been claimed to be other than a province of China by the authorities either in Peking or Taipei. Thus recognising Taiwan as an independent country would place the international unions in the strange position of giving Taiwan a status not claimed for it by any international authority including the United Nations and UNESCO, or even by its own administration. Although this is a course of action that was taken by

several of the unions (eg the International Astronomical Union in 1958), such a decision withdrew the right of the Academia Sinica in Nanking to represent a part of China which it had previously represented and in my view thereby often violated the statutes of the union.

Such actions took place during the fifties when a successful campaign was instigated by the US State Department to secure the membership of China in the unions for representatives of the Academia Sinica in Taipei. Often the Taiwanese applied and were admitted to membership of unions for which any relevant activity in Taiwan was miniscule or non-existent. The acquiescence of ICSU and its unions in this attempt to isolate the Chinese from the international scientific community is responsible for the bitterness with which many Chinese scientists still view ICSU and the insistence with which they demand that the previous decisions be reversed.

Yours faithfully,

GEORGE K. MILEY

Leiden, Netherlands

No arms link

SIR,—In your 'in brief' column (18 August, page 582) you state that "African National Congress officials are reported as saying that 15 German research institutions, including the Max Planck Institute for Nuclear Physics at Heidelberg, have contributed to South Africa's arms programme". We would like to state that the Max Planck Institute for Nuclear Physics is devoted only to basic research in the physics of nuclear structure and nuclear reactions. This research is completely unrelated to arms production.

Yours faithfully,

U. SCHMIDT-ROHR

*Max Planck Institute for
Nuclear Physics,
Heidelberg, West Germany*

Sunflower: a misnomer?

SIR,—It is commonly believed that the movement of the sunflower (*Helianthus annuus*) is a typically heliotropic movement and that with a certain lag, heads follow the path of the sun across the skies in the wake of its daily east-west movement. Observations on a field of

sunflowers growing in the essentially cloudless Mediterranean summer climate at the Ma'abaroth kibbutz settlement in the Sharon plain in Israel reveal that during the night the extent of sunflower head movement is more rapid than during the day.

At dusk all heads do indeed face west, but by 2 am, before any trace of light on the horizon, all heads had reverted to an east facing position. Calculated average velocity of movement during daylight is $\pm 13^\circ$ per h as against $\pm 26^\circ$ per h in the dark.

Furthermore, when complete rotation towards the east had occurred, by 2 am the heads were held at $\sim 40^\circ$ – 45° above the horizontal and upon the appearance of the sun heads 'nodded' eastwards to the extent of a further 15° , as if slightly bowing to greet the rising sun, and only subsequently started their daily journey westwards.

These observations suggest an endogenous 'spring' mechanism, apparently wound up by the sun and released in the dark or light period. The fact that the night movement is twice as rapid as that of the day seems to support the concept that the 'spring' release occurs in the dark and the winding in the light since unhindered mechanical spring release is presumably more rapid than winding, which demands active energy input. If, however, in the future the converse proves to be true, botanists may possibly reach the conclusion that the designation 'sunflower' (of similar etymology in most languages) may be a misnomer and in its stead 'nightflower' may be suggested.

Yours faithfully,

YA'ACOV Y. LESHEM

'The Iron Sun'

SIR,—Roman Znajak, in his review of my book *The Iron Sun* (30 June, page 867) suggested, no doubt unintentionally, that I had misquoted Einstein. In fact, I had made a proof-reading error. The passage in Einstein's *The Meaning of Relativity* to which I had wanted to draw attention is on page 26 of the 1973 Chapman and Hall Science Paperback edition.

Yours faithfully,

ADRIAN BERRY

Predators that switch

from Robert M. May

PREDATION is an important factor in enhancing the diversity of plant and animal communities. One classic example of the way predation can promote coexistence among competitors that would otherwise not persist together is Paine's (*Am. Nat.* **100**, 65; 1966) study of what happened when the dominant predator (a starfish, *Pisaster*) was systematically removed from an intertidal community of marine invertebrates: in less than 2 years, the community collapsed from 15 to 8 species. A variety of other broadly similar examples, from communities on the land and in the sea, have been drawn together by Connell (in *Ecology and Evolution of Communities*, (eds Cody & Diamond) Harvard University Press, 1975).

Suppose we have two or more competing species, one of which would exclude the other in the absence of predation. One pervasive mechanism whereby a predator can enable these competing prey species to coexist is by directing a disproportionately large amount of its attention to the prey species that happens to be most abundant at any one time. This 'switching', to concentrate attacks largely on the most common prey species, may be a simple consequence of the predator's searching behaviour; for example, many predators form a 'search image', which is likely to be set by the locally most abundant prey species. Such patterns of 'switching predation' are common among vertebrate predators (Holling *Can. Ent.* **91**, 293; 1959; Murdoch *Ecol. Monogr.* **39**, 335; 1969), and also among many invertebrate ones (Murdoch & Oaten *Adv. ecol. Res.* **9**, 1; 1975; Hassell Lawton & Beddington *J. Anim. Ecol.* **46**, 249; 1977).

There is no doubt that predation with switching exerts a generally stabilising effect on the dynamics of a community. Elementary accounts of the phenomenon are, however, liable

to two common misapprehensions, which several recent papers have helped to clarify.

The first misunderstanding concerns the extent to which switching predators contribute to the overall stability within the single trophic level of the competing prey species. Too often, simple accounts portray switching as a kind of Universal Stabiliser. In fact, as first emphasised by Steele (*The Structure of Marine Ecosystems*, Harvard University Press, 1974), although switching in a 1-predator/ n -prey system (in which one species of predator preys on n species of prey) will tend to stabilise the competitive interactions, it can result in overall instability if each individual 1-predator/1-prey system is by itself unstable. Steele lucidly combines qualitative reasoning, analytic results and a computer simulation to show that in this case the internal dynamics within the prey trophic level will settle to some stable state (some stable proportion of each prey species), but nonetheless the overall prey/predator system remains subject to the basic instability manifested by the individual prey/predator interactions. Steele's discussion is for overlapping generations, with differential equations; another illuminating study is by Comins and Hassell (*J. theor. Biol.* **62**, 93; 1977), who consider a 1-predator/2-prey system with non-overlapping generations obeying difference equations. In the model discussed by these authors, it can be seen explicitly that predator switching enlarges the domain of parameter space wherein the two prey species can coexist, yet it has no influence on the boundaries of the domain of parameter space wherein the overall prey/predator system is stable. These themes are succinctly summarised by Murdoch (*Am. Nat.* **111**, 383; 1977).

The second misunderstanding concerns the extent to which generalised predation, without any switching, can help competing species to coexist. In very simple mathematical models

(where all prey have the same intrinsic growth rate) a perfectly generalised predator, which attacks all prey species in impartial fashion, makes no difference to competitive coexistence among the prey; the internal dynamics within the trophic level of the prey is unaffected by predation of this evenhanded kind (Van Valen *J. theor. Biol.* **44**, 19; 1974; May in *Some Mathematical Problems in Biology* **6** (ed. Cowan) Amer. Math. Soc., Providence, Rhode Island, 1974). But a small amount of switching behaviour on the part of the predator alters this situation, and can make possible a significantly greater degree of 'niche overlap' among the competing prey species than would otherwise be possible (Roughgarden & Feldman *Ecology* **56**, 489, 1976; Janson, in manuscript, 1975; Murdoch and Oaten, *op. cit.*). Roughgarden and Feldman's study is a particularly clear and rigorous account of the way predator switching can permit increased niche overlap among the prey; yet at least one recent publication quotes it as affirming the broader and unqualified conclusion that "predation increases niche overlap."

Of course, predation can modify the basic conditions under which competition takes place, even if there is no switching. Thus generalised predation may promote coexistence if, among the prey, the less able competitors have higher intrinsic growth rates. Specific examples arise in pastures subject to 'predation' by grazing. Here species diversity can be increased because plants that would be shaded out, or otherwise outcompeted, are given a chance. Harper's (in *Diversity and Stability in Ecological Systems*, US Natn. Bur. Standards, Springfield, Virginia, 1969) review of such situations includes deliberate and accidental (following myxomatosis) experiments where rabbits were withdrawn, and controlled experiments in pastures grazed by sheep. Paine's example is of this general kind.

The above discussion (despite its

pedantic nit-picking) is directed mainly at affirming that predation in general, and particularly predation with switching, can make it easier for prey species to coexist, and thus lead to communities that are more diverse at the species level. If we shift our perspective to focus on the coexistence of different genotypes within a single prey species, analogous considerations arise. By concentrating its attacks on the most common genotype, a switching predator can enable the rarer genotype to enjoy higher fitness; this amounts to 'frequency-dependent natural selection', and is a powerful mechanism whereby genetic polymorphism can be stably maintained. This case has been argued by Clarke (*Sci. Am.* **233** (2), 50; 1975), who emphasises that predator switching is only one of a variety of biologically plausible ways in which frequency-dependent natural selection may be realised. □

Two-faced neurones

from Key Dismukes

THE classic concept of neuronal operation—dendritic summation of synaptic inputs, generation of all-or-none action potentials, propagation along axons, and release of neurotransmitter from terminal boutons—increasingly seems to be an oversimplification. For several years evidence has been accumulating for an array of information processing operations that go beyond the framework of traditional neuronal doctrine (Schmitt, Dev & Smith *Science* **193**, 114; 1976). In the retina, for example, the dendritic projections of axonless local neurones interlace with the synaptic connections of other cells communicating bidirectionally without the use of action potentials.

Recent biochemical studies suggest that the traditional view of the neurone as transmitting information in only one direction will have to be modified. The dopaminergic cells of the substantia nigra have provided the most striking evidence, recently reviewed by L. Iversen (at the Neurosciences Research Program Study Program at Boulder, Colorado in July (to appear in *The Neurosciences: Fourth Study Program* (eds Schmitt & Worden) MIT Press), in whose laboratory much of the work has been done.

Cytochemical studies in several laboratories have indicated the presence of dopamine and the enzymes of its bio-

synthetic pathway not only in cell bodies of the substantia nigra, but also in dendritic fields. This surprising discovery raised the suspicion that dopamine might be released from dendrites, in addition to its normal secretion from axon terminals. To investigate this possibility, Iversen's group studied the release of dopamine from nigral tissue *in vitro* by applying the superfusion chamber techniques that have been widely used to elucidate mechanisms of neurotransmitter secretion. In contrast to the usual conditions, the tissue in these experiments contained no axon terminals bearing the transmitter being studied (the dopaminergic axons of the substantia nigra terminate remotely, in the forebrain). Thus, if dopamine release occurred, it would have to be from the dendrites and/or the cell bodies.

Dopamine was in fact found to be released from the substantia nigra, in a fashion closely paralleling that seen in the neostriatum, which does contain dopaminergic nerve terminals (Geffen *et al.* *Nature* **260**, 258; 1976). Depolarising tissue fragments by raising the external concentration of K^+ produced a substantial efflux of dopamine. This efflux was blocked by removing Ca^{2+} from the superfusion medium, or by Mg^{2+} concentration. Ca^{2+} flow is known to be a central mechanism in neurotransmitter release; thus dopamine efflux from substantia nigra satisfies one of the major criteria for distinguishing the specific secretion of a transmitter molecule from nonspecific leakage through membranes.

Most of these experiments were performed by labelling endogenous dopamine pools with 3H -dopamine and following the appearance of radioactivity released into the superfusion fluid. This was possible because the substantia nigra possesses a high-affinity uptake mechanism for dopamine. This is an interesting fact in itself, because these specialised uptake systems are generally associated with nerve terminals, and are thought to provide a means of inactivating transmitter molecules released into the synaptic cleft. Verification of the results obtained with 3H -dopamine *in vitro* was obtained by using a highly sensitive radioenzymatic assay to demonstrate the minute efflux of endogenous dopamine released by depolarisation. Release of dopamine from substantia nigra has recently been directly demonstrated *in vivo*. Nieoullon *et al.* used push-pull canuli to superfuse the substantia nigra with 3H -tyrosine and to monitor the efflux of 3H -dopamine synthesised intracellularly (*Nature* **266**, 375; 1977). As in *in vitro* experiments, elevated K^+ concentration stimulated the release of 3H -dopamine.

Does dopamine released from the substantia nigra come from dendrites or from cell bodies? That question was answered by making use of the segregated topography of this nucleus. Dopaminergic cell bodies are confined to a central *zona compacta*, whereas dendritic processes invade both that zone and the surrounding *zona reticulata*. 3H -dopamine was taken up and released by depolarisation in both regions indicating that dendrites are indeed capable of secreting neurotransmitter.

What are the targets of dopamine released from the substantia nigra? Evidence suggests that one possibility is the GABA-containing axons from the striatum which terminate in the substantia nigra. Dopamine was recently reported to stimulate the overflow of 3H -GABA from nigral tissue *in vitro* (Reubi, Iversen & Jessell *Nature* **268**, 654; 1977). This stimulation was blocked by antagonists of dopamine, or by lowering Ca^{2+} concentration, indicating that the effect was specific.

Iversen also reported that modulation of GABA release from striato-nigral terminals is also suggested by lesion studies. Neural responses to dopamine seem generally to be mediated by cyclic AMP, whose formation is controlled by adenylate cyclase linked to dopamine receptors. Lesions of striato-nigral pathways containing GABA were found to cause disappearance of dopamine-sensitive adenylate cyclase in the substantia nigra. In contrast, destruction of substance P pathways or of dopaminergic cells themselves did not reduce activity of this adenylate cyclase.

Aghajanian and Bunney have shown that microiontophoretic application of dopamine to the substantia nigra *in vivo* inhibits the firing of dopaminergic cells (Neunyn-Schmeidebergs *Archs Pharmac.* **297**, 1; 1977). This finding, coupled with the GABA studies, suggests a functional role for dendritic release of dopamine. GABA should inhibit the firing of dopaminergic cells in the substantia nigra. Dendritic release of dopamine, by stimulating GABA release from pre-synaptic terminals, could provide a local feedback mechanism to modulate the activity of dopaminergic neurones.

Morphological features suggest that dopamine may be released from dendrites by a different mechanism from that in axon terminals. Iversen reported that electron micrograph studies give no suggestion that dopamine-bearing dendrites contain synaptic vesicles. (This raises a puzzling question about the function of Ca^{2+} , whose role in secretion is believed to involve triggering extrusion of vesicle-bound

transmitter). Nor is there any indication that dopaminergic dendritic elements form synaptic connections with other cells. However, several authors have suggested, on the basis of morphological evidence, that amine neurotransmitters in the brain can be released nonsynaptically (Chan-Palay *Cerebellar Dentate Nucleus* 418-425, Springer Verlag, Berlin, 1977, and references therein). This mode of secretion could be aimed at more distributed targets, and might represent a form of communication intermediate between the exclusive addressing of synapses and the broadcasting of hormones.

Giant molecular clouds

from M. G. Edmunds

A workshop on Giant Molecular Clouds in the Galaxy was held at Gregynog Hall, Newtown, Wales from 8-13 August 1977. It was organised by University College, Cardiff.

THE recent rapid growth in knowledge of the distribution of the carbon monoxide (CO) molecule in the Galaxy by observation of its line radiation at millimetre wavelengths has led to the discovery of a new and very significant component of galactic structure; the Giant Molecular Cloud. The importance of CO is as an indicator of the otherwise virtually unobservable hydrogen molecule H_2 . Where CO forms, it is expected that H_2 will also form, and since hydrogen is by far the most abundant element in the Galaxy, the CO maps can trace the overall density of the interstellar medium. The result of surveys such as those outlined by P. M. Solomon (Stonybrook, New York) suggest that there exist very large 10-80 pc clouds of molecules with masses which are typically 10^5 solar masses and may even reach as high as 10^7 solar masses. Of particular importance have been new maps in ^{13}CO radiation which do not suffer from the severe optical depth uncertainties of ^{12}CO but confirm the large masses of the clouds. The densities are high in these clouds, on average about 700 molecules per cubic centimetre, compared with a value of perhaps one atom per cubic centimetre in the general interstellar space between the clouds.

M. G. Edmunds is in the Department of Applied Mathematics and Astronomy at University College, Cardiff.

Infectious provirus synthesised *in vitro*

from Robin Weiss

ON page 122 of this issue of *Nature* Ellen Rothenberg and her colleagues describe the *in vitro* synthesis of infectious DNA of murine leukaemia virus. Although this feat of high fidelity reverse transcription was first announced more than a year ago, and this paper comes as no surprise, it does mark the culmination of several years investigation of reverse transcriptase activity *in vitro*. The successful transfection of a retrovirus by DNA extracted from infected cells was first achieved by Hill and Hillova (*Nature new Biol.* **237**, 35; 1972) and it constituted a formal proof of Temin's DNA provirus hypothesis. Now the MIT laboratory's improved techniques have yielded complete DNA transcripts *in vitro* which show single-hit dose response for infectivity.

The infectivity of the transcripts is resistant to protease and ribonuclease but is completely destroyed by deoxyribonuclease. The structure of the infectious DNA molecule is curious. It appears that a full-length negative strand is synthesised and shorter segments of positive-strand DNA are formed in duplex with it. Transcripts synthesised in the presence of actinomycin D are not infectious; whether this is attributable to the absence of positive-strand DNA or to incompleteness of the negative-strand transcripts is not clear. The data and their significance are so clearly presented that any further commentary here is superfluous.

The importance of the clouds lies not only in their being easily the most massive individual objects in the galactic disk, but also because they are regions of very active star formation.

The actual number of these clouds in the Galaxy was a matter of some contention, depending to some extent on whether the giant clouds are regarded as a single gravitationally bound system, with complex subcondensations, or as a superposition of smaller independent subunits as proposed by M. Gordon (US National Radio Astronomy Observatory). Most participants were content to accept that each cloud really is a single large complex, and the probable number would then be of order 1,000-4,000, constituting the major part of the mass of interstellar material in the Galaxy. The clouds are not uniformly distributed, showing a very marked 'ring' structure with a concentration of the clouds between 4 to 8 kpc from the centre. It is inter-

esting that the distribution of clouds has not yet been shown convincingly to indicate spiral structure in the disk, although A. Pedlar (Jodrell Bank) claimed some slight evidence from a formaldehyde molecule survey. The Galactic Centre itself is the other major concentration of molecular clouds, a fascinating complex reviewed by N. Scoville (University of Massachusetts) containing as much as 10^7 to 10^8 solar masses, with recent data indicating that a model with an expanding spiral pattern extending right in to the centre may be more attractive than previously proposed expanding disk models.

The formation of stars in the molecular clouds is clearly demonstrated by the existence of infrared sources, caused by the inevitable heating of gas and dust as it collapses under its mutual gravitational interaction, and further heating once the stars have started nuclear energy generation. One obvious site for star formation in the clouds is the characteristic small 'cores' where higher than average temperatures and densities indicate that collapse may be taking place. Much evidence was presented that although low mass stars may form throughout the clouds, the high mass stars over about 12 solar masses form only near the edge of the clouds. B. Elmegreen (Harvard University) and C. Lada (Center for Astrophysics, Cambridge, Massachusetts) claimed this as good evidence for a mechanism of inducing the collapse of further protostars at the edges of the clouds by the effect of compression between shock and ionisation fronts driven into the clouds by radiation, once one bright massive star has formed. The existence of ionised hydrogen regions at the edge of molecular clouds seems very common, and F. Israel (Caltech) presented evidence that most bright, dense regions are of this type, with ionised radiation eating its way into the cloud.

But the mechanism which actually drives the typical subcondensation of a cloud into a state where it will collapse into a star, or cluster of stars, was the subject of much discussion. The effects of the shock wave from a supernova explosion was championed by G. Assousa (Carnegie Institution, Washington), and shocks induced by stellar winds from massive stars maintained as a possibility by L. Blitz (Columbia University) when presenting CO maps of many local molecular clouds. P. Woodward (Leiden) described his extensive numerical calculations of the collapse of clouds induced by the passage of the large-scale density-wave pattern which is believed to maintain a spiral structure in the Galaxy. He received some support from

Elmegreen's observation of what looks like a temporal star formation sequence along the Galactic plane from an infrared source at one end of a giant molecular cloud to a young ionised hydrogen region M17 at the other end of the cloud. But the star formation in many other clouds, such as Orion, shows no particular preference for the direction along the Galactic plane.

Probably all of the mechanisms, and simple cooling or collisions, are important in instigating the collapse of the clouds. Once collapsing it is possible that the collapse phase may be fairly insensitive to the inducing mechanism. Attempts to follow the subsequent dynamical and chemical evolution described by A. Glassgold (University of Oxford) and others are idealised and have not yet reached the stage where they can be reliably compared with observation. The effects of magnetic fields are beginning to be incorporated, but the particular physical and chemical conditions peculiar to the molecular clouds must also be incorporated.

Very small scale structure in the star-forming areas of the clouds can be obtained by observations of radio lines of molecules, such as H_2O , SiO and OH , formed under maser conditions. D. Downes (Bonn) showed some beautiful very-long-baseline-interferometry H_2O maser maps of several molecular clouds compiled by American-German-Russian-Swedish collaboration. The maps show detail down to milliarc s, corresponding to sub-Solar System sizes in molecular clouds. Downes proposed that the best interpretation of the motion of the clusters of masering regions is as the effect of the shell containing the masers expanding and breaking up after the formation of a star at the centre. Scoville, in looking at the high velocity gas observed in ^{13}CO mapping of the Orion molecular cloud, proposed on energetic grounds that an explosion must have occurred (perhaps a supernova) since radiation pressure from a massive star would be insufficient to drive the matter outwards without the infrared luminosity of the source exceeding its observed value.

Complex molecules may be of great relevance for the composition of interstellar dust. F. Hoyle and N. C. Wickramasinghe (University College, Cardiff) proposed polysaccharides, possibly formed by surface polymerisation of the common formaldehyde molecules, as excellent candidates to explain the 10, 3 and $3.4\text{ }\mu\text{m}$ features observed in the infrared spectra of compact sources. They also suggested that organic ring structures may explain the $2,200\text{ }\text{\AA}$ ultraviolet feature in the interstellar extinction curve. Support for the idea that a fairly volatile component

does indeed produce the $2,200\text{ }\text{\AA}$ feature was provided by Israel, who described a preliminary analysis of ultraviolet satellite observations of the galaxy M101 which suggests that the feature vanishes near young hot stars, an effect already noticed in the 30 Doradus nebula in the Large Magellanic Cloud.

Not all star-forming molecular clouds in the Galaxy are massive. Elmegreen described a complex in NGC 7023 of about 1,000 solar masses, and M. Walmsley (Bonn) a molecular cloud in Taurus of only about 1 solar mass. In both these clouds, low mass star formation seems to be occurring.

Many questions were necessarily left unanswered. How do the massive clouds form? Why are they such long-lived structures, with their estimated lifetimes greatly exceeding the expected gravitational collapse time, yet allowing some star formation to proceed? Giant Molecular Clouds have established themselves as a primary component of the Galaxy, and their study will provide many clues in understanding the mechanism of star formation. □

Actin cables

from Roger Craig

THE view that muscles contract by a sliding of the actin filaments past the myosin filaments is firmly entrenched in our minds. So beautifully does it explain both structural and biochemical observations, that the possibility that actin or myosin in non-muscle cells might perform in any different way has, until recently, hardly been countenanced. But actin, for one, does now seem to function in some cells in a distinctly non-muscular fashion.

In muscle, actin occurs as filaments—helices of globular actin monomers—which function in two intimately related ways: as structural components able to bear tension, and as activators of the energy-releasing ATPase cycle of myosin. In non-muscle cells actin can occur in different forms depending on the immediate and local needs of the cell. One of the most important of these seems to be cables of parallel filaments, which are found in intestinal microvilli, in tissue culture cells, in the acrosomal process of some invertebrate sperm, in the cytoplasm of plant cells, and in many other situations.

Although myosin occurs in association with actin in many non-muscle cells (although generally in minute

amounts), there are some cells rich in actin where myosin has not been detected. The question therefore arises: does actin perform a non-motile role in some cells, or does it perform a motile function without the participation of myosin? Actin cables should provide some answers to these questions: since they are a different structural state of actin from that found in muscle, it would not be surprising if they also differed functionally.

What are the structural advantages of a tightly packed cable of actin filaments? The most obvious is one of rigidity: filaments bound together laterally will form a much more rigid structure than an array of unconnected filaments. Such a structure should be able to support a compressive load in addition to the tensile forces actin can sustain in muscle contraction. The finding of a criss-cross network of such cables in many cells has led several authors to suggest that actin in some instances may fulfil a purely structural role, as part of a cytoskeleton which maintains cell shape and strength (see Clarke & Spudis *A. Rev. Biochem.* **46**, 797; 1977). An instance where actin seems to have a motile ability not dependent on myosin is the acrosomal reaction of some invertebrate sperm (Tilney in *Molecules and Cell Movement* (eds Inoué & Stephens), Raven Press, New York, 1975). The acrosomal process, which penetrates the outer layers of an egg during fertilisation, forms rapidly, growing up to $90\text{ }\mu\text{m}$ in only 10 s; and it consists essentially of a beautifully ordered cable of actin filaments. Two mechanisms for the acrosomal reaction have been demonstrated. In echinoderm sperm the process develops by the organisation of actin into the filamentous form from an amorphous state. In the horseshoe crab *Limulus*, the cable is preformed but coiled in the head of the sperm. The process is extended by a rearrangement of the filaments in the cable, which emerges from the tip of the sperm.

Cables of filaments are clearly an important form of actin in non-muscle cells. A recent paper by DeRosier *et al.* (*J. molec. Biol.* **113**, 679; 1977) is therefore significant since it provides the first detailed insight into the molecular structure of cables from two different sources: the acrosomal process of horseshoe crab sperm, and extracts from sea urchin oocytes. Filaments lie parallel to each other, closely packed in a hexagonal array, and in both cases occur in association with another protein of molecular weight 55,000 (not tubulin) which crosslinks adjacent filaments. The cables are extremely regularly organised, appearing like the filtered images of actin paracrystals, and are thus well suited

Roger Craig is a Muscular Dystrophy Association postdoctoral fellow at Brandeis University.

METEOR streams are elliptical rings of dust containing a myriad of particles all moving with orbits very similar to that of the comet which ejected them as it decayed. The stream particles move through the general Solar System dust cloud which is made up of particles with random orbits. Cloud particles were once in streams but they have been perturbed from their specific orbits by interparticle collisions, close approaches to planets and radiation effects.

The Earth passes through many of these streams each year at relative velocities of between 11 and 74 km s⁻¹. Stream particles which hit the atmosphere burn up, forming visual meteor trains (shooting stars) if they are 0.1 g or more in mass, or radio meteor trains (detectable as reflectors of radar pulses) if they have masses greater than 10⁻⁷ g. Smaller stream particles are more difficult to observe. Some space-vehicle experiments have reported large increases in microparticle fluxes associated with streams. However, extrapolations of radio meteoroid fluxes to smaller masses indicate that streams contain very few of these particles. It has been suggested that the satellite borne detectors are registering micrometre-sized lunar ejecta produced by the impact of larger stream meteoroids.

Over the past few years a new method of observing meteor streams has been suggested which relies on detecting the solar radiation reflected by the orbiting stream dust particles. These should scatter radiation in a similar way to the particles in the Solar System dust cloud. The scattering from this cloud produces the zodiacal light and the streams should produce localised enhancements in this light. The problem can be approached in two ways. A. C. Levasseur-Regourd and J. E. Blamont (*Space Res.* **15**, 295; 1975) measured the zodiacal light brightness using the French satellite D2A. They found localised enhancements of brightness at specific points in the Earth's orbit. They concluded that these variations were caused by a

New look at meteor streams?

from David W. Hughes

local excess of scatters produced by the Earth's passage through a meteor stream. The photometer can point in nine directions which are all in a plane perpendicular to the Earth-Sun line. The field of view is about 3° × 3°. Sometimes the enhancement only occurred in one direction, at others in two diametrically opposite directions and in certain cases the enhancement could be detected all around the satellite. From year to year enhancements were found at the same time and in the same directions. The brightness usually increases by about 25% (that is, by between 10 and 50 S₁₀(V) units on a signal of 140 S₁₀(V) this lasting for between 1 and 17 days). (A brightness of 1 S₁₀(V) unit is equivalent to the brightness produced by having one star of visual magnitude +10.0 per square degree of the field of view or an energy flux of 1.31 × 10⁻⁸ erg cm⁻² s⁻¹ star⁻¹ Å⁻¹). The authors conclude that the average size of the inhomogeneity in the plane of view is about 0.15 AU. By assuming that the particles in the meteor stream have the same size and reflecting properties as sporadic zodiacal cloud particles and by measuring the spatial extent of the stream of scatters Levasseur-Regourd and R. Dumont (*COSPAR, XX Plenary meeting, Tel Aviv, paper III C.3.2.*) could estimate the ratio of the particle number density in streams to that outside. This ratio was found to be as high as 18.

W. J. Baggaley of the University of Canterbury, New Zealand, approaches the problem from another direction. He uses the known properties of the particles in meteor streams and considers how effectively they will produce zodiacal light enhancements. His theoretical calculations are given in a recent edition of *The*

David W. Hughes is a Lecturer in the Department of Physics, University of Sheffield.

Observatory (**97**, 123; 1977). Meteor stream dust is optically thin, the particle number density being so low that mutual eclipsing is rare. During an Earth-stream interception (which occurs every time we have a meteor shower) an observer looking in the direction of the true geocentric shower radiant will be observing tangentially to the stream orbit and his line of sight will intersect a large volume of dust particles. The numbers of micrometre-sized particles present have been estimated by extrapolating from particle size distribution measurements made using radar techniques. Using experimentally determined phase functions and an albedo of 0.1 Baggaley integrates along the tangent and calculates the brightness that should be observed in the geocentric radiant direction. For the Quadrantid, Perseid and Geminid streams these brightnesses are 0.57, 3.44 and 1.09 S₁₀(V) units respectively. The total sky brightnesses in these directions, caused by zodiacal light, integrated starlight and atmospheric airglow are 178, 222 and 229 S₁₀(V) units. So the streams theoretically produce an increase of at most 1.5%. The bright patches of light should be elliptical in shape because meteor streams are more dispersed in the plane of the orbit than normal to this plane (by a factor of about 10). The Quadrantids, Perseids and Geminids would produce bright patches of maximum angular extent around 10, 10 and 5 degrees respectively.

Baggaley concludes that the major annual meteor streams would not produce any observable radiant glow, assuming of course that the extrapolation of flux *versus* size data is applicable and that the measured spatial particle-number density (about 10⁻¹⁸ cm⁻³) is correct. The fact that Levasseur-Regourd and Blamont do see streams in the zodiacal light indicates that the radio meteor flux and size distribution data must be re-examined. Either that or the collisional fragmentation which perturbs stream particles into the sporadic background changes their reflecting properties.

to analysis by optical diffraction and three-dimensional reconstruction.

Since the filaments lie in a hexagonal lattice, exactly equivalent bonds could be made between each filament and its neighbours if actin subunits were to occur at azimuthal intervals of 60°. Although the non-integral helical symmetry of the actin filaments does not satisfy this condition, the symmetry is such that actin subunits present many different azimuths during one axial

repeat of the structure. By building models of filaments with the symmetries established by optical diffraction, DeRosier *et al.* have shown that the departure from 60° is small at certain points along the filament. Placing these filaments on a hexagonal lattice in the arrangement deduced from the diffraction patterns, they conclude that bonds between filaments can be made at these points if distortions are allowed. The distortions required are

small—of the same order as those discussed by Caspar and Klug for quasi-equivalent bonding between the subunits of spherical viruses (*Cold Spring Harbor Symp. quant. Biol.* **27**, 1; 1962). As pointed out by these authors, such an ordered structure need not have all identical molecules in exactly identical environments. The important point is that the lowest energy structure will have the maximum number of most stable bonds formed—and this may be

physically realised . . . by quasi-equivalent bonding of identical units.'

Support for the quasi-equivalent bonding scheme comes from the oocyte cables. Optical diffraction shows that the filaments repeat after 19 turns of the actin helix containing 41 subunits. The model predicts that 9 of the 41 subunits are appropriately oriented for quasi-equivalent bonding, and the cables reveal nine transverse stripes at the predicted axial positions in each repeat. These are thought to be due to the 55,000 molecular weight protein attaching to and crosslinking actin subunits of adjacent filaments at these points.

In the case of the acrosomal process no transverse stripes are seen. But here every actin is associated with the 55,000 component, not just those involved in crosslinking, so that all morphological subunits look alike. A bonding scheme analogous to that in the oocyte bundles has been proposed, with only those 55,000 components attached to appropriately oriented actins actually participating in crosslinking. The model seems plausible since the bond distortions in this case are less than those required in the oocyte bundles. DeRosier *et al.* have carried out a three-dimensional reconstruction of the acrosomal bundle. This reveals that the 55,000 molecular weight protein is bound to the actin subunit near the myosin binding site. While this may not be significant in a cell thought not to have myosin, it could prove relevant in other systems in controlling the interaction of actin cables with myosin.

This is the first time that actin filament cables from cells have been subjected to such analysis. The results, showing how the 55,000 molecular weight protein binds the filaments into an organised cluster, may be applicable to bundles from other sources—but with caution, since different or additional controls may prevail elsewhere.

Free calcium measurement in cells

from T. J. Lea

An EMBO Workshop on Ca Measurement in Cells was held in Oxford on 8-10 July, 1977.

It was in 1928 that H. Pollack reported that a saturated solution of alizarin sulphonate when injected into amoebae produced a shower of red crystals (Ca alizarinate) in the cyto-

plasm on the initiation of pseudopod formation. This pioneering attempt to examine cellular changes in free Ca was mentioned at the workshop during discussions of more modern methods. In a three-cornered fight between the users of photoproteins (such as aequorin), metallo-chromic indicators (such as arsenazo III) and Ca-sensitive microelectrodes, limitations of these more recently developed methods were critically examined and it became apparent that no single technique satisfied all the requirements of a good indicator of free Ca in cells.

On the evidence of results achieved, aequorin has until now led the field. Among recent advances obtained with this photoprotein was the demonstration by C. C. Ashley (University of Oxford) and colleagues of a transmitter-like action of L-glutamic acid on barnacle muscle fibres, and Ca-transients in cardiac muscle (D. G. Allen, University College London). The related indicator obelin has been used in sarcoplasmic reticulum vesicle by D. W. Yates (University of Bristol) and A. K. Campbell (Welsh National School of Medicine, Cardiff) in an attempt to measure Ca uptake by the vesicles. This method does suffer from the disadvantage of a fairly rapid consumption of the photoprotein by Ca entering the vesicles. An undoubted highlight of the meeting was the presentation by L. Jaffe (Purdue University, Indiana) on aequorin-injected eggs of the medaka, a freshwater fish. Jaffe and his colleagues succeeded in showing that immediately following fertilisation, a Ca-wave crosses a single egg (1 mm diameter) from the point of entry of the sperm and reaches the opposite side within two minutes. He concluded that because the wave is unaffected by Ca-free media, its mechanism involves a calcium-induced Ca release from some internal sites, and this idea was certainly of interest to muscle physiologists present in the audience.

The problem of quantifying the Ca measuring methods especially in relation to resting free Ca in cells was an important theme throughout the meeting. Allen produced evidence of a Ca-independent light emission from aequorin *in vitro* which he claimed gave a theoretical detection limit for free Ca in cells of 6×10^{-8} M with a practical limit of 3×10^{-7} M. Since A. Scarpa (University of Pennsylvania) and P. F. Baker (King's College, London) estimated the free Ca in squid axons using aequorin to be 2×10^{-8} M and 6×10^{-8} – 15×10^{-8} M respectively, this particular claim aroused some objections. However, in

general, new data given by Allen and Ashley on the shape of the aequorin–Ca calibration curve and its dependence on cytoplasmic ions, such as Na^+ , K^+ , H^+ and Mg^{2+} , should improve the accuracy of free Ca determinations made with this photoprotein.

In the opinion of I. Parker (University College, London), the absorbance indicator arsenazo III is superior to aequorin for measuring rapid transient changes in free Ca, such as those in the sarcoplasm and nerve endplate of a frog muscle fibre during a single twitch. The response time is faster, although how much faster seemed to be disputed, and the free Ca is linearly related to the absorbance change. For longer term events such as muscle tetani, he felt arsenazo to be inferior because of large movement artefacts, drift in the optical record and unexplained 'tail effects' at the end of the event. L. H. Pinto (Purdue) reported the successful use of purified arsenazo in *Limulus* photoreceptors, but found that concentrations of the dye greater than 3 mM in the cell caused changes in the membrane response to light pulses, which could be explained by arsenazo buffering of cell Ca. The strong dependence of the arsenazo absorbance on Mg^{2+} and H^+ was also emphasised by several speakers. The limit of Ca detection by arsenazo was put at $\sim 10^{-7}$ M by J. D. Owen (University of Utah, Salt Lake City).

Of the three methods, the Ca-selective microelectrode has achieved least in the field so far, but it has much to offer, particularly in the measurement of free Ca in small cells. The use of new compounds embedded in PVC membranes gives the electrodes a linear response down to 10^{-6} M free Ca, while as low as 10^{-8} M can be detected (Owen). In fact R. Meech (University of Cambridge) reported a value for the free Ca in snail neurones very similar to that of Owen's ($\sim 10^{-7}$ M corrected for Mg^{2+}) without the help of a Ca microelectrode, using instead the reversal potential of the Ca-dependent K current. Attempts to measure Ca changes during a single action potential have not so far been successful (G. Christoffersen, Copenhagen) partly because of the slow response time of these electrodes (1–2 s). □

Correction

In the article 'Meteorite research old and new' (*News and Views* 268, 691; 1977) column 3, paragraph 2, 6 lines from end should read: "Serra de Magé minerals probably did not become closed systems until 4.42 Gyr ago," not "4.52 Gyr ago."

The mean lifetime of orthopositronium in vacuum

T. C. Griffith & G. R. Heyland*

Various measurements and calculations of the vacuum lifetime of ortho-positronium have given widely divergent values. There are indications that these differences are now gradually being resolved.

POSITRONIUM, the hydrogen-like atom formed when an electron and a positron are bound with a ground state binding energy of 6.8 eV, has lately become the subject of intensive study in several laboratories. It is readily formed when positrons emitted from a radioactive source are moderated to energies comparable with those of the valence electrons in atomic and molecular gases or in solid surfaces especially those of certain oxide powder grains such as MgO or SiO₂. The positronium atoms exist as either *para*-positronium, *p*-Ps, the singlet state with total spin zero or *ortho*-positronium, *o*-Ps, the triplet state with unit spin. Since the positron is the antiparticle of the electron positronium has no permanent existence; the two particles eventually annihilate one another and the probability of annihilation from the bound states can be evaluated. It is found that *p*-Ps is very short lived with a mean lifetime for decay of its ground state into two collinear γ rays, each of energy 0.511 MeV, of only 0.125 ns. Its short lifetime renders it more difficult to observe directly than *o*-Ps whose ground state, to conserve spin, has to decay into three coplanar γ rays of total energy 1.022 MeV with a mean lifetime of about 140 ns. Apart from the vacuum lifetime several other properties of positronium have been extensively investigated. After several attempts, spanning a period of about twenty years, the characteristic Lyman- α radiation from the 2P-1S transition in *o*-Ps was eventually detected by Canter *et al.*¹. There has also been a number of observations on the fine structure (or hyperfine structure) splitting of the ground state of positronium.

Theoretical background

Theoretical and experimentally-determined values of the mean lifetime for the decay of *o*-Ps in free space, which is the main subject of this article, have recently undergone considerable variation. Evaluation of this parameter involves the basic principles of quantum electrodynamics, because to high order the constituent particles interact only through the electromagnetic interaction. Its evaluation and measurement provide a clean test of quantum electrodynamics. A full formulation of the problem was presented by Strosio and Holt² and by Strosio³ and an expression was given for this mean lifetime, which includes the radiative corrections corresponding to all order terms in the fine structure constant α_f , in the form

$${}_o\lambda_p = {}_o\lambda_p(0)[1 + (\alpha_f/\pi)(1.86 \pm 0.45)] \quad (1)$$

where ${}_o\lambda_p(0)$ is the lowest order rate given as

$${}_o\lambda_p(0) = \frac{2\pi\alpha_f^6 m_e c^2}{h} \frac{2(\pi^2 - 9)}{9\pi} \quad (2)$$

and ${}_o\lambda_p$, the decay constant, is the reciprocal of the *o*-Ps mean lifetime. m_e is the electronic mass, c the velocity of light and h is Planck's constant.

Before these calculations only the lowest order rate had been evaluated and the initial value of $7.14 \mu\text{s}^{-1}$ given by Ore and Powell⁴ was used until the improved accuracy of α_f resulted in its upgrading to $7.2112 \mu\text{s}^{-1}$ about ten years ago. The all order calculation, Strosio³, gave ${}_o\lambda_p = (7.242 \pm 0.008) \mu\text{s}^{-1}$ which remained as the best theoretical value until the recent calculations of Caswell *et al.*⁵ who reported a much lower value of ${}_o\lambda_p$, their expression being

$$\begin{aligned} {}_o\lambda_p &= {}_o\lambda_p(0)[1 - (\alpha_f/\pi)(10.348 \pm 0.070)] \\ &= (7.0379 \pm 0.0012) \mu\text{s}^{-1} \end{aligned} \quad (3)$$

The historical sequence of events relating the above calculations to progress with the laboratory measurements, given in Table 1, has been an interesting demonstration of the importance of cross-checking and verification of results by independent research groups.

Measurement techniques—gas method

None of the measurements of ${}_o\lambda_p$ carried out before those of Beers and Hughes^{6,7} and of Coleman and Griffith⁸ were sufficiently precise to warrant higher order calculations but the improvement of experimental techniques since that time has been such that measurements to an accuracy approaching 0.01% can now be contemplated. The measurements of ${}_o\lambda_p$ performed before 1976 were taken using methods based on a linear extrapolation of the *o*-Ps decay rates, λ_p , in a given gas at different densities, to zero density according to the relationship

$$\lambda_p = {}_o\lambda_p + q\rho \quad (4)$$

where ρ is the gas density in amagats (1 amagat = 2.69×10^{19} molecules cm^{-3}) and q the quenching coefficient which defines

Table 1 Values for the decay rate of positronium

Year	Value of ${}_o\lambda_p$ (μs^{-1})	Comment

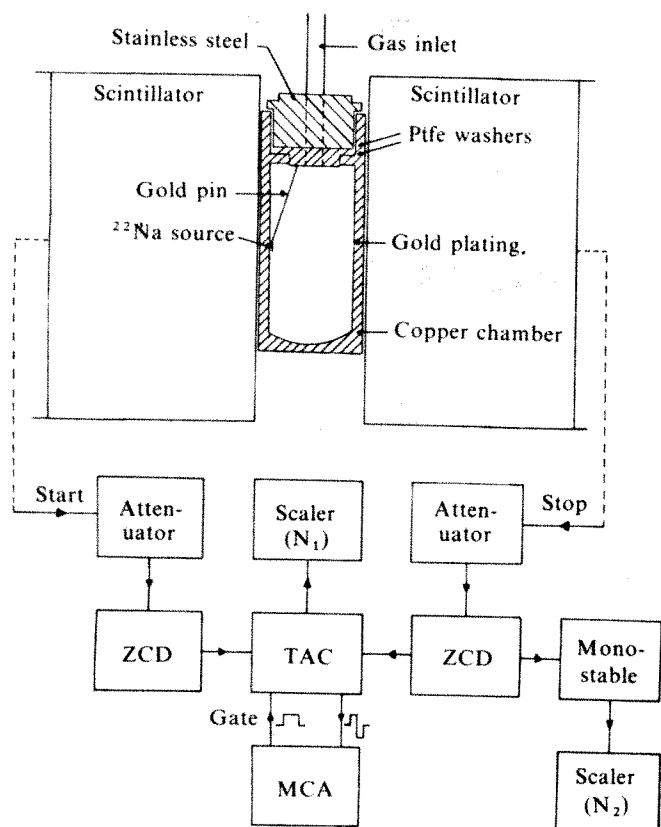

Fig. 1 Positron lifetime apparatus of Coleman *et al.*¹¹ with block diagram of the electronics. (ZCD, zero crossing discriminator; TAC, time-amplitude-converter; MCA, multi-channel analyser. N_1 and N_2 are the 'start' and 'stop' counting rates).

the increase of the decay rates, λ_p , due to collisions between the *o*-Ps atoms and gaseous molecules. The constancy of q has been established for many gases so that a linear extrapolation of equation (4) at low densities is justified.

The main features of the gas extrapolation methods are explained by reference to Fig. 1, where a schematic diagram of the lifetime apparatus of Coleman *et al.*¹¹ is given. Positrons from a ^{22}Na source were moderated in the gas contained in a small copper vessel internally gold plated to enhance back-scattering of positrons into the gas. The time interval between the emission of a positron and its subsequent annihilation is measured for a large number of events to give the positron lifetime spectrum. The 1.28 MeV γ ray emitted simultaneously with the positron is detected with one plastic scintillation counter and provides the start pulse for a timing sequence which is terminated by a pulse from the second counter which detects one of the annihilation γ rays. The lifetime spectrum of about 10^8 events accumulated in 24 hours will generally have components corresponding to the annihilation of free positrons and *p*-Ps as well as the decay of *o*-Ps. The experimental conditions for the determination of λ_p are arranged so that the component due to *o*-Ps is dominant with all the other components compressed into a narrow prompt peak near $t = 0$. This is achieved by choosing a gas, or mixture of gases, for the experiment to satisfy the following criteria: (1) high probability for formation of positronium (2) rapid thermalisation of those positrons which have not formed positronium (3) fast decay rate for the thermalised free positrons (4) small value of q (5) large molecular weight to ensure high stopping power. A mixture of ammonia-Freon 12-helium in the proportion 42%, 42% and 16% respectively, used by Griffith *et al.* (unpublished) with the above apparatus, satisfied most of these requirements and it was found that 50% of the positrons in the gas formed *o*-Ps. Even at the lowest densities the free positrons decay so rapidly that the lifetime spectrum, as shown in Fig. 2, consists of a narrow

prompt peak followed by a single exponential due to *o*-Ps decay. λ_p is derived from a distribution $D(t)$ expressed, to a good approximation, as

$$D(t) dt = [A \exp(-\lambda_p t) + B] dt \quad (5)$$

where $D(t) dt$ is the observed number of events in the time interval between t and $t+dt$ and both A and B are constants. In situations where this approximation is not valid Coleman *et al.*^{12,13} have given an exact formulation of the problem. Accurate background subtraction is very important especially for data at low densities where the signal to background, defined at A/B at $t = 0$, is low and typically varied from 31 at high density to 7 at low density in the experiment of Griffith *et al.* (unpublished).

The earlier measurements of Beers and Hughes⁶ were taken with a similar type of apparatus to that described above. They used Freon-12 alone and also a mixture of Freon-12 and argon but points below 1 amagat were not consistent with a linear plot. This non-linearity was attributed to *o*-Ps quenching at the vessel walls. Coleman and Griffith⁸ also used Freon-12 in a similar type of experiment but did not experience any difficulties at their low density points. Their ratio of A/B varied from 5 to 2 and the method of background subtraction, although more detailed than for earlier experiments, was not as accurate as that of Griffith *et al.* (unpublished). The use of the method of 'direct detection', described by Coleman *et al.*¹², to give high counting rates was a new feature in the system of Coleman and Griffith⁸. Instead of using the prompt 1.28 MeV γ ray to produce the start pulse for the timing sequence they detected the fast positrons from the ^{22}Na source in a thin plastic scintillator (of thickness 0.015 cm) as they entered the gas in the chamber. This method gave a value of λ_p which was in agreement with that of Beers and Hughes^{6,7} and also with the calculations of Strosio and Holt².

Other methods

The method of Gidley *et al.*⁹, illustrated in Fig. 3 was also based on the principle of 'direct detection'¹². Instead of producing the *o*-Ps by moderation of fast positrons in a gas they used very fine grains of SiO_2 powder as moderator. A high yield of posi-

Fig. 2 Typical lifetime spectrum for an ammonia-freon-helium mixture at a density of 0.79 amagat units. Curve (a) represents the raw data and curve (b) the *o*-Ps component after background subtraction. For clarity only alternate data points have been plotted. $A/B = 9$, $\lambda_p = 7.396 \pm 0.007 \mu\text{s}^{-1}$. Total number of *o*-Ps events = 6×10^6 .

tronium from positrons moderated in the oxide powders MgO , SiO_2 and Al_2O_3 was first reported by Paulin and Ambrosino¹⁴ when they measured a decay constant of value close to λ_p for such powders in vacuum. This observation suggested that there was very little quenching of the o -Ps trapped in the interstices between the powder grains. Gidley *et al.*⁹ used grains of uniform size and assumed that the quenching was proportional to the collision rate of the o -Ps atoms with the grains. A parameter analogous to density in the gas experiments was defined as $\rho_s[\rho/\rho_s - \rho]$ and represented the mass per unit free volume of the powder. Accordingly λ_p was plotted as a function of

Fig. 3 Schematic diagrams of the positron "direct detection" system of Gidley *et al.*⁹ for the SiO_2 powder lifetime experiment.

$\rho/(\rho_s - \rho)$ where ρ_s is the solid aggregate density of 2.20 g cm^{-3} and ρ the powder density which was varied by compression over a range from 0.03 to 0.26 g cm^{-3} . Their results (see Fig. 4), show straight lines for two different grain sizes extrapolating to the same zero density value of $\lambda_p = 7.104 \pm 0.006 \mu\text{s}^{-1}$ which was substantially lower than all the earlier measurements and theoretical predictions. The timing sequence in this experiment was similar to that used in the gas experiments. Their efficient detection of all the positrons entering the powder through a 0.5-mm -thick plastic scintillator from a ^{68}Ge source ensured values of A/B ranging from 300 to $2,000$ depending on the method adopted for producing the stop pulse from the annihilation γ rays. Analysis of the data using equation (5) was therefore accomplished to a high degree of accuracy. In common with the experiments at other laboratories precise methods were used for the time calibration of the system and a variety of tests were devised to ensure that their data was not affected by systematic errors.

The large discrepancy with previous measurements and theoretical calculations revealed by the above experiment prompted Gidley *et al.*¹⁰ to design an experiment for the direct measurement of λ_p in vacuum. The apparatus for this new experiment is illustrated in Fig. 5 and the method is based on the production of positronium from a beam of low-energy positrons as was done by Canter *et al.*¹ in their experiment to detect the positronium Lyman- α radiation. About 500 slow

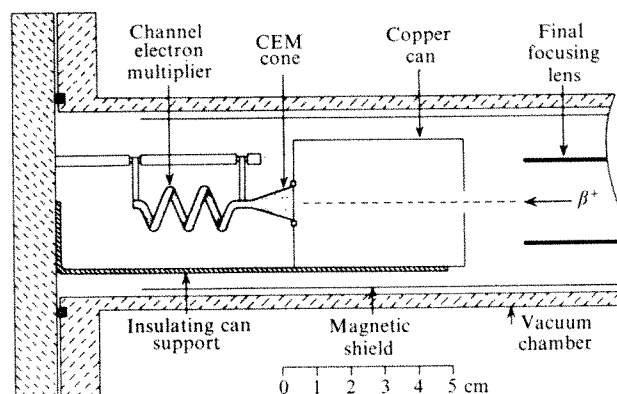

Fig. 4 O -Ps decay rates in SiO_2 powder, by Gidley *et al.*⁹, as a function of the parameter $\rho^* = \rho/(\rho_s - \rho)$ defined in the text. Curves are given for two different grain size. All samples were evacuated to 10^{-6} torr. and outgassed at 350°C for 4 h .

positrons per second, from a $46 \text{ mCi } ^{58}\text{Co}$ source followed by a gold- MgO moderator, were accelerated to 400 eV and transported down a 1 m flight path and focused through a 6-mm diameter aperture on to the MgO -coated cone of a channeltron electron multiplier. Positronium is formed on the cone with 15% efficiency and allowed to diffuse back into the evacuated copper can whose inside walls were also coated with a thin layer of MgO to reduce quenching and confine the positronium to a region for which the efficiency of detection of the annihilation γ rays is approximately uniform. The detectors were shielded from γ rays directly from the source. Backscattered positrons from the cone were stopped from entering the can by biasing the cone to -400 V and the can to -50 V . The stop pulse of the timing sequence was generated from the annihilation γ rays in the same way as for the earlier experiment⁹ but the start pulse was derived from the secondary electrons emitted simultaneously with the positronium from the channeltron cone. The lifetime spectrum was again represented by equation (5) with λ_p now replaced by λ_p measured directly and, depending on the method used to derive the stop pulse, the A/B ratio ranged from $1,500$ to $9,000$. Their data, of the same form as illustrated in Fig. 2, gave a mean value of $\lambda_p = 7.09 \pm 0.02 \mu\text{s}^{-1}$ which was in good agreement with their previous measurement⁹.

The meaning of recent results

The recent calculated value of $\lambda_p = 7.0379 \pm 0.0012 \mu\text{s}^{-1}$ by Caswell *et al.*⁵ strongly suggested that the measurements of

Fig. 5 Apparatus used by Gidley *et al.*¹⁰ for the direct determination of λ_p for o -Ps in vacuum.

Fig. 6 The *o*-Ps decay rate λ_p as a function of gas density, ρ , for an ammonia–freon–helium mixture measured by Griffith *et al.* (unpublished). The errors are smaller than the circles enclosing the points. The numbers in parentheses represent the ratio A/B at those densities.

Gidley *et al.*^{9,10} could be closer to the true value than those obtained in the earlier experiments. This view is now reinforced by the new low value obtained in the improved gas extrapolation method of Griffith *et al.* (unpublished). Their values of λ_p , shown in Fig. 6, carry very small statistical errors and lie on a good straight line extrapolating to $7.058 \pm 0.15 \mu\text{s}^{-1}$, a value which is smaller than all the previous measurements. The gold plating on the inner walls of their vessel, by increasing the number of *o*-Ps events, has improved the A/B ratios by a factor of 5 in comparison with those of Coleman and Griffith⁸. It is probable that the very low values of A/B in the latter experiment⁸ contributed a systematic error which gave a high value of λ_p and a similar argument may apply to the measurement of Beers and Hughes⁶.

The new value of $7.058 \pm 0.015 \mu\text{s}^{-1}$ is currently being subjected to a series of tests to establish that the measurement is

free of systematic errors. At present there is no evidence for nonlinear behaviour even at densities as low as 0.05 amagat units. This implies a negligible amount of quenching of the *o*-Ps on the gold surface. There is some uncertainty about the assignment of gas density from the pressure and temperature of mixtures of molecular gases because the virial coefficients are not accurately known, but at low density this should not be a serious error. Corrections for the mass per unit free volume have not been applied in the gas experiments because the appropriate value of ρ_s is not known. There is no evidence of deviation from a straight line at high densities which would be expected if this correction was significant.

All recent measurements of λ_p lie within the range 7.05 to $7.11 \mu\text{s}^{-1}$ and the true value is probably within these limits or lower. In common with the new gas extrapolation method the experiments of Gidley *et al.*^{9,10} may also be subject to error. In their first experiment⁹ the determination of the powder density is subject to some uncertainty and the way in which the powder packs under compression has not been investigated. Some error might also be expected in their second experiment¹⁰ due to uncertainty about the quenching of *o*-Ps at the surface of the can.

Gidley *et al.*¹⁵ have recently reported that they are also performing a gas extrapolation experiment and their preliminary values of λ_p are reported to be in agreement with their earlier values. It is clear that very accurate values of λ_p will soon be available from more than one laboratory and that the recent theoretical calculations of Caswell *et al.*⁵ will be closely tested.

Positions of galactic X-ray sources: $20^\circ < l^{\text{II}} < 55^\circ$

R. E. Doxsey, K. M. V. Apparao*, H. V. Bradt, R. G. Dower & J. G. Jernigan

Department of Physics and Center for Space Research, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

Precise positions, determined with data from the SAS-3 X-ray observatory, are presented for eight galactic plane X-ray sources (*Aq1 X-1*, *Ser X-1*, *3U1956+11*, *3U1822-00*, *3U1915-05*, *A1845-02*, *A1850-08*, *A1905+00*). Error radii for the positions range from 20 to 50 arc s. Previously proposed optical identifications of three of the sources (*Ser X-1*, *3U1956+11*, *A1850-08*) are supported by these results. Three (*Ser X-1*, *A1905+00*, *3U1915-05*) have been identified as X-ray burst sources.

THE rotating modulation collimator (RMC) system on the SAS-3 X-ray observatory has been used to carry out a systematic survey of the galactic plane ($|b^{\text{II}}| \lesssim 10^\circ$). The aim of the survey is to identify galactic X-ray sources by the precise measurement of their positions (error radii $< 60''$). A few preliminary results based on small amounts of quick-look data have been previously reported¹. The availability of production data and a more complete calibration of the instrument now allows a more thorough, sensitive,

The circle is centred at the average position and has a radius equal to the r.m.s. scatter of the points (7"). + indicates the position of the optical counterpart. *b*, Calibration residuals for the 2.3' collimator. The data for each calibration observation has been analysed and plotted as in *a*. The circles representing the r.m.s. scatter of points about the average positions have been overlayed with the true position used as a registration point. The r.m.s. scatter of the average positions from the true position is 12". The 20" dashed circle represents the error radius for a source position limited only by systematic errors.

and more accurate survey than previously possible. We discuss here the instrument calibrations and present results of the analysis for the region $20^\circ < l < 55^\circ$. This region has been previously surveyed with the UHURU (ref. 2) and Ariel V (ref. 3) satellites.

The SAS-3 RMC system consists of two independent modulation collimators^{4,5}. One has a periodic triangular response function with a FWHM of 2.3', the other, 4.5'. Both modulation collimators have $12^\circ \times 12^\circ$ FWHM coarse collimators to limit the field of view. Proportional counters sensitive in the range 2–11 keV are used as X-ray detectors. The centre of the overall field of view is aligned with the spacecraft spin axis. RMC survey data are taken with the satellite rotating uniformly about its axis at ~ 1 –2 revolutions per 95-min orbit. Star trackers provide data from which the motion of the spacecraft relative to the celestial sphere can be reconstructed to an accuracy of 5–10".

Accuracy of position determinations

The calibration of the RMC system was determined from observations of several bright, optically identified X-ray sources; in particular Sco X-1, Cyg X-1, and Cyg X-2. These observations have been made periodically throughout the lifetime of the satellite and are designed to cover the range of parameters normally encountered (spin rate and direction, temperature, and location of source in field of view). These data have also been used to investigate the short and long term stability of the star tracker-collimator system.

Two orientation angles and the collimator periodicity define completely the transmission response of a modulation collimator over its entire field of view. The two angles required are the rotational orientation of the collimator about the spacecraft spin

axis and the phase of the spin axis perpendicular to the periodic transmission bands. If the true celestial position of the source in the field of view is known, then a set of linearised least square fits to the data can be used to determine these angles. The data from two observations of Sco X-1 (19–20 May 1975 and 9–10 July 1975) were used in this way. Each satellite orbit of data was independently analysed and fit to determine the three parameters. The average value of each parameter for each collimator was then fixed for use in the subsequent analyses.

X-ray source positions are obtained from a computation of the cross-correlation between the data and the expected response for a two-dimensional grid of sky points⁶. A grid separation of $\sim 1'$ is used to compute a 'map' of the central region ($15^\circ \times 15^\circ$) of the field of view. Precise positions are obtained from a high resolution map ($\sim 1''$ grid) in the local region of a source. Subtraction of the Bessel function patterns of the bright sources often reveals fainter sources, not noticeable in the original map⁶.

The two Sco X-1 observations were used to test the mapping algorithm and the reproducibility of the position determination on a short (~ 1 d) time scale. Sco X-1 is sufficiently bright so that the effect of counting statistics on the measured position is negligible ($< 1''$) for a one-orbit exposure. The correlation map technique was applied independently to each orbit of data. The r.m.s. scatter of positions relative to the average position was 7" for one Sco X-1 observation (Fig. 1a) and 9" for the other. We believe that this scatter of the positions is due to small random errors in the star tracker attitude solution since the orbit-to-orbit variations for the two collimators are highly correlated. The offset (5") between the average position and the optical counterpart reveals a systematic error.

Fig. 2 Line drawings of regions containing X-ray sources reported in this paper. U, UHURU error boxes²; A, Ariel V error boxes³; S, SAS-3 error circles. In cases where two SAS-3 error circles are shown, the larger is the previously reported quick-look result.

*Averaged over the observation and accurate to $\sim 10\%$. We quote the flux density at 5.2 keV of an incident power-law energy spectrum with slope $\alpha=1.08$ (for example, the Crab nebula²³). 1.0 μ Jy corresponds to 2.2×10^{-11} erg s^{–2} (2–11 keV). $I=1.060$ μ Jy and 1.0 RMC count s^{–1} = 2.7 μ Jy.

The systematic errors were further evaluated with a comparison of the average positions determined for Cyg X-1 and Cyg X-2 and the true positions (Fig. 1b). We find an r.m.s. scatter of 12" in the difference between true and measured positions for both collimators. This is larger than can be accounted for either by counting statistics or the random attitude solution error. The errors are not consistent with a correlation between the calibration parameters and temperature, satellite age, or spin rate. There is no set of values for the calibration parameters which will reduce this scatter. Therefore, we adopt the calibration parameters determined from the Sco X-1 data for the analysis of the survey data.

The error radii for X-ray source locations are determined from an evaluation of four sources of error: counting statistics, random aspect errors, systematic errors, and errors resulting from the subtraction of bright sources. Each of these errors is modelled as a Rayleigh distribution (two-dimensional Gaussian). The contribution due to counting statistics is $\sigma_1 = 1.7 \delta N_T^{1/2} N_S^{-1}$, where δ is the FWHM of the collimator (2.3' or 4.5'), N_T is the total number of counts recorded, and N_S is the number of X rays detected from the source. The factor 1.7 is calculated from the specifics of the cross-correlation computation and has been verified empirically. The contribution due to systematic errors is $\sigma_2 = 12''/2^{1/2} = 8.5''$ (for a Rayleigh distribution, $\sigma = \theta_{r.m.s.} 2^{-1/2}$). The random aspect error is $\sigma_3 = 10''(2n)^{-1/2}$, where n is the number of orbits of data in the observation. Since n is generally greater than 10, this term is usually negligible. The error resulting from the subtraction of a bright source is $\sigma_4 = 0.6 \delta/f$, where f is the ratio of the intensity of the faint source to the intensity in the same region of the residual ripples from the bright source after subtraction. This ratio must be evaluated for each source; in most cases $f > 30$ and $\sigma_4 < 5''$.

The 90% confidence error radius for the combined error is then $E_r = 2.15 (\sigma_1^2 + \sigma_2^2 + \sigma_3^2 + \sigma_4^2)^{1/2}$. This radius ranges from $\sim 60''$ for a source near the detection threshold to $\sim 20''$ for a source limited only by systematic errors. A source position and its associated error are calculated for each collimator from all the data taken with the satellite spin axis at one location relative to the source.

We usually obtain several pairs of independent position determinations by observing each source from a number of different spin axis locations. The quoted position is the weighted average of the positions determined for each observation. The quoted error radius is representative of the error radii computed for the

individual observations. An empirical error radius, E_r' , is calculated from the scatter of the determined positions. We have found so far good agreement between E_r' and our chosen error radius. If, occasionally, we do not find them to be comparable, we will adopt the larger value.

Results

The region of the galactic plane between longitudes 20° and 55° was observed 11–16 July 1975, immediately after one of the observations of Sco X-1, and also on 13 September 1975. The spin axis was pointed for 1 d at each of six 'targets' in the region. The overall

field of view was larger than the separation between targets, so each source was detectable in the data from at least two independent observations. Earth blockage, South Atlantic anomaly penetration, and partial loss of daytime star tracker data reduced the usable data in each of these observations to $\sim 30,000$ s.

A total of eight previously known X-ray sources were detected in this region. The positions determined for these sources are given in Table 1. Error circle radii were determined as discussed above. The contribution to the total error radius from the random aspect and

source subtraction errors was negligible for all of these sources. In all cases, the scatter in the positions determined from independent observations was less than the computed error radius. Source intensities (2–11 keV) are averaged over the one day observation and are accurate to $\sim 10\%$. The positions are plotted relative to previous results in Fig. 2. Finding charts for each of the sources are provided in Fig. 3. Table 2 contains celestial positions and magnitudes estimated from image diameters² for several stars in each finding chart.

Fig. 3 Finding charts for the SAS-3 positions. The charts are taken from the Palomar Sky Survey blue plates (National Geographic Society). North is up and east is to the left. The indicated scale factor applies to all charts. Stars are numbered to ease communication between observers. Letter designations indicate proposed identifications (see text).

There are 11 sources detected in the UHURU and Ariel V surveys of this region which we have not seen. If these sources were at their catalogued intensities, then only one, 3U1901+03, should have been clearly above our detection threshold. Another one, 3U1912+07, would have been above our threshold if it were at the intensity reported in the 3U catalogue², but below our threshold at the intensity reported by Seward³.

The current status, with regard to the identification of these objects, is as follows:

3U1822-00: there have been no proposed candidates for this source. There are no stars visible on the Palomar Sky Survey blue plate in the error circle and only a few on the red plate.

Ser X-1: Davidsen⁸ proposed a candidate for Ser X-1 based on the SAS-3 quick-look results⁹. The object is a faint ($B \approx 18.5$) star with an ultraviolet excess. It is $\sim 4''$ from the centre of our refined error circle. Ser X-1 is also a source of X-ray bursts¹⁰⁻¹², the first burst source for which a stellar counterpart has been proposed.

A1845-02: There have been no proposed candidates for this source. The source lies in a heavily obscured region. There is only one star visible on the Palomar Sky Survey inside the error circle.

A1850-08: The globular cluster NGC6712 was proposed by Seward³ *et al.* as a possible counterpart for A1850-08. Cominsky *et al.*¹³, using UHURU data, and Grindlay *et al.*¹⁴, using ANS data, improved the position determination of this source. In both cases, NGC6712 was consistent with the data, but field objects could not be ruled out. Our position for this source clearly identifies it with the cluster. The centre of the cluster is $\sim 30''$ from our best position, well inside the error circle. Of the known variable stars in the cluster, two long period variables, V2 and V8, lie within the error circle. Also lying within the error circle is V17, which was seen to vary by Harwood¹⁵, but not by Sandage¹⁶ or Rosino¹⁷.

A1905+00: there are currently no proposed candidates for this object. The source has been identified as an X-ray burst source^{11,18}.

Aql X-1: a candidate for Aql X-1 was proposed by David-

sen¹⁹ based on the UHURU error box. This candidate is ruled out by our results.

3U1915-05: The star 26f Aql, suggested as a possible counterpart in the 3U catalogue² is not consistent with our results. This source was first proposed as a burst source candidate by Becker *et al.*²⁰ based on OSO-8 observations (error box area $\sim 13 \text{ deg}^2$) and has been confirmed with recent SAS-3 observations (error box area $\sim 0.1 \text{ deg}^2$ (ref. 24)).

3U1956+11: Margon *et al.*²¹ have proposed a candidate for this source based on the SAS-3 quick-look results²². It has a B magnitude of 19.0 with a spectrum similar to that of Sco X-1. It lies $10''$ from our present refined position.

We thank the staffs of the Center for Space Research at M.I.T. and the Goddard Space Flight Center. Stellar coordinates were measured at facilities of the Kitt Peak National Observatory. This work was supported in part by the US NASA. This is the second in the series of articles on positions of galactic X-ray sources with SAS-3 (ref. 1 being the first).

Supernovae, grains and the formation of the Solar System

James M. Lattimer

Department of Astronomy, University of Illinois, Urbana, Illinois 61801

David N. Schramm & Lawrence Grossman

The Enrico Fermi Institute, University of Chicago, Chicago, Illinois 60637

The observed ^{26}Mg and ^{16}O anomalies in meteorites can be consistently understood if a supernova occurred within a few million years of the condensation of the Solar System. Grains condensing in the ejecta from this supernova may be an integral aspect of this process.

THE detection^{1,2} of excess ^{26}Mg which correlates with the Al/Mg ratio in a Ca-rich inclusion in the C3 chondrite Allende offers strong evidence that a nucleosynthetic event preceded the formation of the Solar System by at most a few million years. Two explanations for the production of ^{26}Al , which decayed to form the observed excess ^{26}Mg , have been presented. (1) An irradiation in the early Solar System³ could synthesise the observed amount of ^{26}Al throughout a solar nebula of $1 M_{\odot}$, but the energy required is greater than the binding energy of the Sun. This seems unreasonable large. In addition, excess amounts of other rare isotopes such as ^{40}K and ^{50}V , as well as neutron-induced isotopic anomalies in elements such as Gd, would be produced. No such anomalies have been observed to date. (2) One or more super-

novae, which could produce ^{26}Al in either explosive carbon burning or in a high temperature carbon burning shell source immediately preceding the explosion, occurred near the protosolar cloud⁴. This supernova would have had to occur within a few ^{26}Al decay half lives (7.2×10^5 yr). The fact that the protosolar cloud condensed within such a short time of this supernova may not be accidental; the supernova trigger hypothesis of the formation of the Solar System has been considered by several authors (ref. 4 and S. Margolis, in preparation). We present here the results of our supernova grain condensation calculations and relate them to the hypothesis that a 'last event' supernova was indeed related to the formation of the Solar System and thus might have created the observed isotopic anomalies in magnesium, oxygen, neon and xenon.

Four components of presolar material are envisaged for the formation of the Solar System. The first two, interstellar gas and dust, have been enriched by supernova and nova debris (gas and possibly dust) and stellar winds, among other processes, throughout galactic history. The average composition of the dust may be chemically and isotopically different from the gas. The last two

components, 'last-event' supernova gas and dust, may be mixed into the protosolar cloud when the shock wave from this supernova collides with the cloud and initiates its collapse. We note here, in reference to the problem of producing observable isotopic anomalies, that it may be easier for the 'shrapnel-like' grains from the supernova to penetrate to the interior of the cloud than for supernova gas. This gas, part of which mixes by Rayleigh-Taylor 'interfingering' at the interface between the expanding supernova shock front and the protosolar cloud, may mostly just pass around the exterior of the collapsing presolar nebula. In addition, the time required for injected supernova gas to completely mix with nebular gas may be so short that production of non-radiogenic isotopic anomalies with supernova gas alone might be precluded.

The currently accepted model⁶ of presupernova stars pictures them to be composed of several layers. The outer layer has roughly 'solar' composition, while successive interior shells have compositions corresponding to the products of static hydrogen, helium, carbon, oxygen and silicon burning, respectively. The supernova occurs when the presupernova core collapses, and a shock wave explosively burns and ejects the outer layers of the star. In some stars, however, the shock wave may not cause significant explosive processing. Because the most complete estimates of the composition of supernova ejecta are explosive burning calculations, we assume that these ejecta contain zones composed, successively, of the products of explosive hydrogen, helium, carbon, oxygen and silicon burning. These zones are hereafter referred to as the (H), (He), (C), (O) and (Si) zones.

Table 1 shows, for each explosive burning zone, the isotopic compositions⁷⁻⁹ of the major elements that are decidedly non-solar. Entries are of three types: first, the oversynthesis of one or more isotopes of an element, relative to the others, compared with solar isotopic abundances (namely ^{32}S , ^{33}S , ^{40}Ca and ^{42}Ca in the (C) zone); second, the survival of only one isotope of an element (namely ^{16}O and ^{24}Mg in the (O) zone); or, third, the enhancement of the neutron-rich isotopes of an element relative to solar abundances due to neutron capture during explosive burning or the static helium burning¹⁰ phase that preceded explosive carbon and oxygen burning (namely Ti in the (He) zone).

To discover what minerals could condense in supernova ejecta, equilibrium condensation calculations for each of these zones have been performed¹¹. The results for 10^{-8} atm pressure and different C/O and (S + Si)/O ratios are also shown in Table 1. We have listed, for reasons discussed below, only those minerals that are also condensible at 10^{-3} atm, assuming either that $T > 1,430$ K and C/O < 1 or $T > 1,300$ K and C/O > 1, and otherwise solar¹² abundances. The calculations are not very sensitive to pressure

changes. The most important compositional parameter is the C/O ratio, or, in the (Si) zone, the (S + Si)/O ratio. Grains condensed from a given zone will have an isotopic composition characteristic of that zone and are hence capable of carrying that composition into the presolar nebula. But it is not at all certain that grains can form in expanding supernova ejecta. Preliminary estimates¹¹ suggest that grain condensation is only possible if the shock wave that explosively burns and ejects the matter is relatively weak. If grains do form these results indicate their probable compositions.

As the collapse of the presolar nebula proceeds, the pressure and temperature rise. If isotopic anomalies are to be carried into the Solar System in grains, these grains must be able to survive, that is, their composite minerals must be condensible in this physical environment. We are primarily interested in Ca-rich inclusions of C3 chondrites, which seem to have formed in a nebular region that had a maximum pressure of about 10^{-3} atm and a roughly solar¹² composition. The maximum temperature, T_{max} , that this region reached must have been greater than the condensation temperature of forsterite¹¹, 1,430 K, because the bulk chemical compositions of the Ca-rich inclusions are similar to those calculated for the pre-forsterite condensate and dramatically different from the post-forsterite composition. If $T_{\text{max}} > 1,742$ K, no major O-bearing mineral could survive. But corundum (Al_2O_3), perovskite (CaTiO_3), melilite [$\text{Ca}_2(\text{Al}_2, \text{MgSi})\text{SiO}_7$], spinel (MgAl_2O_4) and diopside ($\text{CaMgSi}_2\text{O}_6$) could survive if $T_{\text{max}} < 1,742, 1,681, 1,625, 1,530$ and $1,435$ K, respectively. Because all these minerals could condense in at least two supernova zones, isotopic anomalies in the elements O, Mg, Si, Ca and Ti may eventually be observable in Ca-rich inclusions.

Excess ^{16}O (ref. 13) and ^{26}Mg have been observed in these inclusions and could have been carried into the solar nebula in grains condensed in the (C) zone (Table 1). In addition, excess ^{16}O is also produced in the (O) zone. Lee *et al.*² found that there is a positive linear correlation between the excess ^{26}Mg and the Al/Mg ratio, that is, the data define an Al-Mg isochron. Clayton *et al.*¹³ found the amount of excess ^{16}O to be fairly constant within a given phase, even from samples taken from different inclusions. Both observations may be easier to understand on the basis of a gaseous rather than a crystalline source of these anomalies. But textural¹⁴ and trace element¹⁵ evidence imply that these inclusions were at least partially melted during or after their formation. Since diffusion in silicate melts is more rapid than in crystalline silicates, all phases crystallising from or equilibrating with a melt would tend to have the same isotopic composition, thus obliterating any previous distribution that could be used to ascertain the source of these anomalies. Those phases which did not melt would be

expected to have different isotopic compositions. Experiments¹⁶ have shown that spinel and pyroxene have higher minimum melting temperatures in this system than melilite and anorthite. Observations¹³ show that the spinel and pyroxene of Ca-rich inclusions have greater concentrations of excess ¹⁶O than melilite, by about a factor of four. This could be explained by a partial melting of the inclusions at a time when there was less excess ¹⁶O in the ambient gas than in the inclusion. On the same grounds, one could expect deviations from the Mg-Al isochron to occur. But, the higher melting point phases (spinel, pyroxene) have such small Al/Mg ratios that relatively large differences in their initial ²⁶Al/²⁷Al ratios would, considering the experimental uncertainty², be unobservable. Thus, the determination of the source of the Mg and O anomalies will be difficult since we may not see the original distribution of ²⁶Al and excess ¹⁶O.

One other distinction remains between the Mg and O anomalies. While the ²⁶Al has to be associated with a nucleosynthetic event that occurred within a few million years of the Solar System's formation, the observed excess ¹⁶O does not. Since the (C) and (O) zones produce excess ¹⁶O, either 'old' presolar grains or 'last-event' supernova grains could have carried excess ¹⁶O into the presolar nebula. But, if grains cannot form in supernova ejecta, the only remaining way, in our scenario, to inject excess ¹⁶O is through last-event supernova gas.

The ²²Ne anomaly¹⁴ observed in CI chondrites may have been produced by 2.6 yr ²²Na-bearing presolar grains condensed in the (He) zone¹⁹. In the solar nebula these grains vaporise if $T_{\max} > 1,000$ K. But evidence²⁰ suggests that CI chondrites may have formed in nebular regions where $T_{\max} < 400$ K; if decay-produced ²²Ne can be retained in or on these grains at this temperature, incorporation of excess ²²Ne into CI chondrites may occur. But, irradiation¹⁷ in the early solar nebula could also produce excess ²²Ne with energy requirements far less stringent than those for the production of ²⁶Mg by irradiation.

What minerals could survive in the presolar nebula if the composition was solar except for a C/O ratio > 1 ? Enstatite chondrites apparently condensed in such a region²¹. Unfortunately, less is known about the mineralogical history of enstatite chondrites, so no limits on T_{\max} can at present be imposed. Calculations¹¹ show that if $T_{\max} > 2,025, 1,930, 1,745, 1,458, 1,400$ and $1,390$ K, respectively, TiC, C, SiC, Fe₃C, AlN and CaS could survive: all of these phases can be condensed in at least two supernova zones (if C/O > 1 in the appropriate supernova zones). Thus, C, N, S and Fe, in addition to Mg, Si, Ca and Ti, isotopic measurements could potentially be key indicators of which supernova zones have been sampled. The C¹²/C¹³ ratio could prove very important in this respect, since this ratio should be less than its solar value if the (H) zone is responsible, while if presolar grains from the (He) and/or (C) zones are incorporated in enstatite chondrites this ratio should be greater than its solar value.

Before the discovery of the ²⁶Mg anomaly, it was thought that

the last nucleosynthetic event affecting the Solar System occurred about 10⁸ yr before its formation²², which is the interval between the production of the r-process radioactive parents (¹²⁹I, ²⁴⁴Pu) of Xe and the retention of daughter Xe in the meteorites. Assuming that the anomalous ²⁶Mg is the *in situ* decay product of ²⁶Al, the Mg timescale is about 10⁶ yr. There are at least two explanations for this discrepancy. First, ²⁶Al, ¹²⁹I and ²⁴⁴Pu may not have been produced in the same nucleosynthetic event, but in separate events 10⁸ yr apart. The latter event made ²⁶Al, but no r-process nuclei (or at least its r-process material did not get into the solar nebula). The incorporation of Al, I and Pu occurred about 10⁶ yr later. The second explanation is that these three nuclei were all made in the same (last) event, but somehow Xe was unable to be retained by meteorites until 10⁸ yr later, possibly because this region of the presolar nebula or the meteorite parent bodies remained too hot. A search for ²³⁵U anomalies due to the decay of ²⁴⁷Cm might resolve this problem²³. ²⁴⁷Cm (half life 1.54×10^7 yr), ¹²⁹I (1.7×10^7 yr) and ²⁴⁴Pu (8.3×10^7 yr) are all r-process nuclei. The U timescale's turning out to be of the order of the Xe timescale would be evidence in favour of the first possibility since U is a refractory element and does not diffuse out of meteoritic minerals as readily as gaseous Xe.

It seems, therefore, that a last-event supernova provides a consistent explanation of the observed isotopic anomalies. Condensation sequences for supernova ejecta imply that presolar grains may be a useful part of this picture.

We thank E. Anders, D. Arnett, R. Clayton, S. Falk and J. Truran for useful discussions. J.M.L. expresses appreciation for the hospitality of both the Institute of Astronomy, Cambridge, England, and NORDITA, Copenhagen, Denmark, where part of this research was done. This work was supported in part by the US NSF (J.M.L., D.N.S.), NASA (J.M.L., D.N.S., L.G.) and by the Alfred P. Sloan Foundation (L.G.).

Three-dimensional model of membrane-bound ribosomes obtained by electron microscopy

P. N. T. Unwin

MRC Laboratory of Molecular Biology, Hills Road, Cambridge, UK

A low-resolution three-dimensional map has been obtained from crystalline arrays of membrane-bound eukaryotic ribosomes. It shows both ribosomal subunits to be adjacent to the membrane surface, attached to it by a part protruding from the large subunit.

Most eukaryotic cells have two populations of actively synthesising ribosomes which are distinguishable morphologically according to whether they exist free in the cytoplasm or are bound to membranes, normally the endoplasmic reticulum. In general, the two populations synthesise different sets of proteins. One function of membrane-bound ribosomes, originally discovered from

Fig. 1 Organisation of crystalline ribosomes and membranes as in the oocyte of *Lacerta sicula* during winter. *a*, Face-on view; *b*, edge-on view. Membrane-bound ribosomes which are separate from those in the crystals (arrows) are also evident ($\times 50,000$). To bring out details clearly, the ribosome-membrane complexes have been isolated from the cytoplasm and suspended in 100 mM KCl, 5 mM $MgCl_2$, 0.25 M sucrose, 50 mM triethanolamine-HCl, pH 7.6. All thin sections were prepared by fixing in glutaraldehyde, post-fixing in OsO_4 , embedding in Araldite, then staining after cutting with uranyl acetate and lead citrate.

experiments with secretory cells¹, is to synthesise proteins for export from the cell. These proteins are vectorially discharged through the membrane during synthesis².

Ribosomes are attached to the membranes by two types of interaction³; one is sensitive to ionic strength and the other to the antibiotic puromycin. The salt-sensitive interaction occurs directly between the large ribosomal subunit and the membrane, but its significance is not yet understood. The puromycin-sensitive interaction is indirect and is thought to be due to an anchoring effect by the membrane on the nascent polypeptide chain. It is therefore associated with proteins which are to be transferred across

the membrane. Recent findings indicate that the specificity for the interaction between the nascent polypeptide and the membrane resides in the amino-terminal sequence of the protein⁴⁻⁷.

It is generally assumed that the large ribosomal subunit lies between the small subunit and the membrane surface^{8,9} and that the protein being synthesised passes into and through the membrane through a protected region^{10,11} within the large subunit. But the electron microscopical and biochemical experiments on which these ideas are based do not provide definitive evidence, and the exact configuration of the ribosome with respect to the membrane is uncertain.

This study is based on a three-dimensional analysis of crystalline arrays of ribosomes which bind to membranes through a salt-sensitive linkage. The commonly assumed configuration is not confirmed. In the crystals, both subunits lie close to the membrane surface, attached to it by a part protruding from the large subunit.

Lizard ribosome crystals

The crystalline sheets of ribosomes which develop in the oocytes of the lizard *Lacerta sicula* during its winter hibernation period¹², were used for this study. Each sheet is composed of two layers of ribosomes which are continuous with the cytoplasm and are bordered on either side by extended, flattened, vesicular membranes similar in appearance to the cisternae of the endoplasmic reticulum. In each layer of a sheet the ribosomes present the same surface to the membrane against which they are juxtaposed, and are arranged as tetramers in the space group P4 ($a=595 \text{ \AA}$) (ref. 13). The crystalline material is inactive *in vivo*, but seems to be competent in protein synthesis when isolated and tested in a cell-free system¹⁴.

Face-on and edge-on views of the sheets are shown in Fig. 1. A detailed description of the packing of the ribosomes seen there and of the crystallographic relations between the layers of a sheet has been given elsewhere¹³. Face-on views (Fig. 1*a*) looked at from an appropriate glancing angle, show either tetramers or single ribosomes to line up in rows. When, in the edge-on views (Fig. 1*b*), the tetramers or the single ribosomes superimpose, they give rise to characteristic patterns of dashed (tetramer) or dotted (single ribosome) lines.

The membranes are most obvious in the edge-on views. They are separated from the densely staining parts of

Fig. 2 Edge-on view of a six-layer stack of sheets formed by aggregation of three single sheets (each of two layers of ribosomes) in a medium of low ionic strength (50 mM KCl, 5 mM $MgCl_2$, 0.25 M sucrose, 50 mM triethanolamine-HCl, pH 7.6) containing 0.25% Triton. The zones from which the membranes have been extracted are indicated by the arrows. The other, darker, zones correspond to the region between the two layers of a sheet. Section $\sim 2000 \text{ \AA}$ thick ($\times 150,000$). Stacks of sheets formed artificially in this way have the same appearance as the 'three-dimensional crystals' of ribosomes which develop, in the absence of membranes, in live chick embryos when they are cooled¹⁵.

Fig. 3 Single ribosomes and tetramers attached to membrane fragments after high salt treatment; negatively stained in uranyl acetate ($\times 55,000$). The following steps were carried out at 4°C . The cytoplasm from about 50 selected previtellogenic oocytes were carefully opened out under a dissecting microscope into about $50\ \mu\text{l}$ of low salt medium ($50\ \text{mM KCl}$, $5\ \text{mM MgCl}_2$, $0.25\ \text{M sucrose}$, $50\ \text{mM triethanolamine-HCl}$, $\text{pH } 7.6$), stirred vigorously, then centrifuged at $\sim 300g$ for 10 min to produce a pellet consisting almost entirely of large aggregates of ribosome sheets and membranes. This pellet was resuspended in $50\ \mu\text{l}$ of high salt medium ($500\ \text{mM KCl}$, $5\ \text{mM MgCl}_2$, $0.25\ \text{M sucrose}$, $50\ \text{mM triethanolamine-HCl}$, $\text{pH } 7.6$), held for 15 min, and then centrifuged at higher speed to remove any large contaminating material. The supernatant, containing the freed ribosomes and membranes was divided into two equal portions, one of which was dialysed against the low salt medium for several hours. Both portions were subsequently examined together in the microscope. Only the dialysed portion contained membrane-bound ribosomes. The few mitochondrial membranes present in these solutions, and erythrocyte ghosts which had been added to them before dialysis, showed no signs of attachment.

the crystalline ribosomes by a narrow, but distinct, zone relatively free of stained material. A zone of the same width is also observed when the membranes have been partially dissolved, indicating that osmotic effects are not responsible for its appearance or its width. No gap corresponding to this zone is found, however, between ribosomes and membranes in the non-crystalline regions. These ribosomes always seem to be more closely attached, as do those on the endoplasmic reticulum.

Biochemical findings

The stain-depleted zone could be taken to indicate that the ribosome crystals are not attached to the membranes but are held apart, for example, by electrostatic forces. Other evidence favoured direct attachment, however: it was not possible to separate the components in detergent-free media of near physiological composition by normal mechanical means. In addition, the appearance of membrane-extracted stacks of sheets, which sometimes form in the presence of the detergent, Triton X-100 (see Fig. 2), seemed to imply that this zone contained some matter.

Two types of experiment gave more compelling evidence. In the first (Fig. 3) the KCl concentration was varied. It was found that the ribosome sheets, which seemed to be strongly attached to the membranes in solutions containing $5\ \text{mM MgCl}_2$ at KCl concentrations of about $100\ \text{mM}$ or less, were all released without difficulty, and dissociated into single ribosomes and subunits, when it was raised to $500\ \text{mM}$. Furthermore, the released ribosomes were competent in attaching specifically to fragments of the same membrane when the KCl concentration was brought down again. As Fig. 3 shows, many, but not all, of the ribosomes which attached on lowering the KCl concentration tended to associate to form tetramers; the crystal bonding between tetramers was not re-established. In the second experiment (Fig. 4), ribosome sheets which had been isolated from the membranes by detergent treatment¹³, were incubated with vesicles of lizard liver endoplasmic reticulum from which

the bound ribosomes had been removed. A large proportion of the surfaces of all sheets then became covered by membranes, as would be expected if the ribosomes composing them were orientated so that their salt-sensitive attachment sites were exposed and available for interaction. A strong association is suggested by the observations that most of the vesicles are drawn out in single membrane layers and that in places where they are only on one side they cause the crystal to bend.

I conclude that the ribosomes are directly attached to the membranes through a salt-sensitive linkage which may well be the same linkage that binds them to the endoplasmic reticulum.

Analysis of isolated sheets

To investigate the three-dimensional structure of the ribosomes in the sheets they were isolated from the membranes as in ref. 13, placed on electron microscope grids and negatively stained with uranyl acetate. Micrographs were then taken of them tilted at angles between 0° and 76° to the incident 100-kV electron beam.

Fourier methods^{17,18} were used to analyse and combine the data from the micrographs. The Fourier transform of one layer of ribosomes is a two-dimensional lattice of lines along which the phases and amplitudes vary continuously. The Fourier transform of an isolated sheet therefore consists of two such lattices, one of which is

Fig. 4 Isolated crystalline sheets of ribosomes, (a), were incubated with vesicles of endoplasmic reticulum (b), giving the result, (c) ($\times 40,000$). Vesicles of endoplasmic reticulum were prepared at 4°C by a procedure similar to that given in ref. 16. Two lizard livers were homogenised in about twice the volume of a medium containing $0.25\ \text{M sucrose}$, $50\ \text{mM triethanolamine-HCl}$, $\text{pH } 7.6$, and centrifuged twice at $15,000\ \text{r.p.m.}$ ($\sim 20,000g$) in a M.S.E. 3X6.5 titanium swing-out rotor, discarding the pellet and scum at the top on each occasion. The supernatant was then layered on to a discontinuous gradient of $1.5\ \text{M}$ and $2.0\ \text{M sucrose}$ in $50\ \text{mM KCl}$, $5\ \text{mM MgCl}_2$, $50\ \text{mM triethanolamine-HCl}$, $\text{pH } 7.6$, and spun at $42,000\ \text{r.p.m.}$ ($\sim 150,000g$) for 20 h, using the same rotor. The slightly opalescent 'rough microsome fraction' was withdrawn from the region near the $1.5\ \text{M}/2\ \text{M sucrose}$ interface and mixed with an equal volume of a high salt medium containing puromycin so that the final concentration was $500\ \text{mM KCl}$, $5\ \text{mM MgCl}_2$, $0.75\ \text{M sucrose}$, $50\ \text{mM triethanolamine-HCl}$, $1\ \text{mM puromycin}$, $\text{pH } 7.6$. This mixture was incubated at 22°C for 30 min to release the ribosomes and then passed through the same sucrose gradient as previously. The ribosome-stripped vesicle fraction was removed from the second centrifugation at a concentration of $\sim 4\ \text{mg}$ of membrane protein per ml. The vesicle preparation was mixed with an equal volume of isolated ribosome sheets in $50\ \text{mM KCl}$, $5\ \text{mM MgCl}_2$, $0.25\ \text{M sucrose}$, $50\ \text{mM triethanolamine-HCl}$, $\text{pH } 7.6$, prepared as before¹³, and incubated for 6 h at 0°C before fixation, embedding and sectioning.

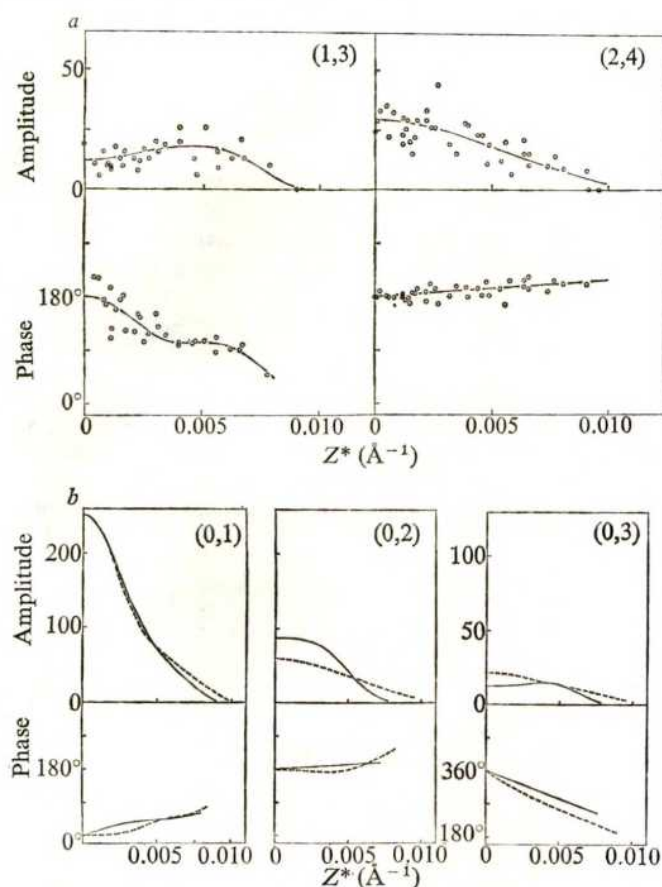

Fig. 5 *a*, Values of calculated amplitudes and phases along two typical lattice lines, plotted as a function of distance (Z^*) from their centres. In this space group the Friedel relationship gives the corresponding values for negative Z^* . Continuous curves drawn through the points and sampled every 0.002 \AA^{-1} give the data on which the three-dimensional map is based. The average phase error, based on comparison of single phase measurements against all others within a small range of Z^* , is less than 20° . Micrographs were taken with a goniometer stage, using bent support grids to achieve the highest tilt angles. They were densitometered and analysed as in ref. 13. The information was combined as in ref. 18. No corrections for effects of defocus were needed at this resolution. *b*, Amplitudes and phases calculated for the $(0,k)$ lattice lines from the tilting experiments (full line) and from edge-on views of superimposed tetramers in $\sim 2,000\text{-\AA}$ thick sections (broken line). The data obtained from the edge-on views have been adjusted to give the best fit with the data from the tilting experiments, the difference between positive and negative staining being accounted for by a 180° phase change. The amplitude scale factor and phase origin adjustment needed to fit the two sets of data were used to correct the variation along the $(0,0)$ lattice line, which the edge-on view gives directly.

upside-down and rotated by a specific amount with respect to the other, depending on the crystallographic relationship between the two layers. Hence, each micrograph gives two sections through the three-dimensional Fourier transform of one layer.

Sixteen micrographs (32 different views of one layer) were needed to give continuous curves of phase and amplitude along all of the 25 crystallographically independent lattice lines, except for the line through the origin, out to a resolution of 90 \AA . Two such curves are shown in Fig. 5*a*. Several micrographs from a given tilt series were suitable for data collection since radiation damage was not a limiting factor.

Optical diffraction patterns from micrographs of negatively stained and (sectioned) positively stained isolated sheets were similar, indicating that at this low resolution, except for the reversal in contrast, positively stained and negatively stained sheets would provide roughly

equivalent maps of the structure. The approximate form of the lattice line through the origin could therefore be determined from sectioned material by calculating the Fourier transform of an edge-on view of one layer. The correct scale of the amplitudes and the origin adjustment for the phases along this lattice line were then found by comparing data, as in Fig. 5*b*.

By sampling the continuous variation of the complete transform at suitably fine intervals (0.002 \AA^{-1}) along the lattice lines, a three-dimensional map of the ribosomes in one layer was calculated.

Three-dimensional map

Figure 6 shows a tetrameric unit from the three-dimensional map, viewed so that the juxtaposed membrane, if it were present, would lie underneath, and also a single ribosome from this unit, viewed parallel to the plane of the array. The contours map out the negative stain-excluding regions only. Therefore they are insensitive to differences of composition within the ribosome and do not show up areas of RNA or protein into which the negative stain may have penetrated.

Particularly noticeable in Fig. 6*a* is a region within the ribosomes which looks like a hole, and so probably represents that part where the large and small ribosomal subunits are most widely separated. The shape and dimensions of the matter surrounding this region resemble features observed in micrographs of isolated eukaryotic ribosomes and of their isolated subunits^{19,20}. A detailed comparison, and arguments based on molecular weight estimates²¹, indicate that the two subunits lie side by side, and suggest that the ribosome can be partitioned as shown, with the large subunit closest to the centre of the tetramer. The line dividing the subunits seems to follow the path in which the inner contours come closest together and connect the 'hole' to the outside, but its exact position cannot be determined from this low resolution map.

Figure 6*b*, the view of a single ribosome along the direction of this path, emphasises another feature of the other map—a narrow protrusion on the large subunit

Fig. 6 Views of *a*, a tetramer and *b*, a single ribosome emphasising the dominant features of the three-dimensional map. The negative contours, representing the stain excluding parts, have been drawn at two levels (-2 and -6 in a scale 0 to -10) and the region within the inner contours has been shaded. The tetramer is orientated so that the juxtaposed membrane would lie underneath (right-handed configuration¹³); it is upside-down in comparison with the usual orientation on microscope grids of isolated tetramers and tetramers in p4 arrays²², where the ribosomes present 'left featured frontal' views^{19,20}; thus the small subunit (S) is on the anticlockwise side, and the large subunit (L) on the clockwise side, of the path (arrowed) connecting the 'hole' to the outside. The single ribosome is viewed from the direction indicated by the arrow; the feature protruding from it was estimated, independently of the map, to extend as far ($\pm 15 \text{ \AA}$) as the dotted line. Scale bars represent 50 \AA .

extending towards the central fourfold axis. From the configuration of the group of four of them, it seems that the ribosomes of a tetramer touch in the region close to the central fourfold axis, as well as at a higher radius. These protrusions are unlikely to be something peculiar to ribosomes which crystallise, since the tetramers can be formed *in vitro* from ribosomal subunits released from polysomes²². Nor are they likely to be membrane proteins, since another explanation would then be required for the identical packing of ribosome tetramers in the non-membrane associated stacks of sheets found in chick embryos when they are cooled¹⁵. They are therefore most probably normal components of the large subunits.

Membrane attachment

Edge-on views of stacks of sheets (Fig. 2) were used to derive, independently of the three-dimensional map, the distance reached by the protrusions in the direction of the membrane. In the membrane-extracted zones of these stacks the protrusions show up as slightly denser areas between the dashed lines formed by the tetramers, and presumably extend halfway into the zones. The half-way distance was estimated from projection maps calculated from Fourier transforms of these views, using the data on which the three-dimensional map is based to obtain the correct scale and to define the centre of a layer. The result of the estimate, the furthestmost distance reached by the protrusions in the direction of the membrane, is indicated by the dotted line drawn in Fig. 6b. The position of this line is consistent with the details in the map.

The line in Fig. 6b could also represent the surface of the membrane with which the crystalline ribosomes are associated *in vivo*, since the open space between the protrusions would then give a zone of the same width as seen in Fig. 1b. No additional material is required to span the space. Therefore the protrusions must be the links by which the crystalline ribosomes establish contact with sites on the membrane surface.

It seems unnecessary to draw a distinction in mode of attachment between the crystalline and non-crystalline membrane-bound ribosomes. The closer association with

the membrane of the latter could be due to some freedom of movement of the ribosomes about their attachment site when they are no longer constrained by the crystal bonding.

It is possible that membrane-bound ribosomes are attached by the same mode—some distance from the body of the ribosome—during the initial stages of protein synthesis. A wide separation between the site where the large subunit binds and the emerging polypeptide should allow the polypeptide freedom of motion relative to the highly fluid^{23,24} endoplasmic reticulum, without greatly disturbing its proximity or orientational disposition. Thus, the main function of this type of attachment could be to give the molecules in the membrane and the protein being synthesised a good chance to interact.

I thank Nichol Thompson for cutting the sections, Dr L. Amos for some computer programs and Drs C. Taddei, R. Henderson and M. Bretscher for helpful discussions. The Philips Application Laboratory Cambridge, kindly made available the goniometer version of their EM400 electron microscope for the tilting experiments.

In vitro synthesis of infectious DNA of murine leukaemia virus

Ellen Rothenberg, David Smotkin,
David Baltimore & Robert A. Weinberg

Department of Biology and Center for Cancer Research, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

DNA synthesised in vitro by purified virions of murine leukaemia virus is infectious. Neither RNA nor protein is required for infectivity. Transfection with reverse transcriptase product shows a single-hit dose response and results in the production of complete, infectious virus.

THE discovery of reverse transcriptase in virions of retroviruses^{1,2} provided a system for studying the viral DNA synthesis which was known to be essential early in infection^{3,4}. Until recently, however, most groups studying reverse transcription *in vitro* found the DNA products to be small relative to the size of the RNA templates. Thus it was not known whether virions could make a complete copy of the

viral genome without the intervention of cellular factors.

Recent studies have improved reaction conditions so as to allow detergent-disrupted virions to synthesise DNA molecules up to 8,000–9,000 nucleotides long, the length of the viral genome RNA which serves as template^{5–7}. It has been possible to synthesise very long DNA transcripts in the 'endogenous reaction' without sacrificing the specificity of initiation: the longest products made by virions of Moloney murine leukaemia virus (M-MuLV) apparently share the unique initiation site and tRNA^{Pro} priming mechanism used by the shorter transcripts^{8,9}. Since the longest transcripts also migrate as a discrete species close to genome length in Agarose gel electrophoresis, it seemed possible that they could be biologically active. We report here that infectious DNA can be synthesised *in vitro* by purified virions of M-MuLV.

Conditions for synthesis of infectious molecules

The conditions used for DNA synthesis were essentially the same as described previously⁶ with a few modifications. Actinomycin D was omitted except where indicated below. A higher yield of the longest DNA molecules was obtained when the ionic strength was reduced to a minimum by omission of NaCl from the reaction mixture and when the incubation was carried out at temperatures between 39 and 41 °C. In most of the DNA preparations used for these studies, each deoxyribonucleoside triphosphate (dNTP) was present at 2 mM. In early studies, DNA was synthesised with each dNTP at 5 mM, but a higher absolute yield of the longest transcripts was obtained with the lower substrate concentration. The lower yield at high substrate concentration was presumably due to the inhibitory effects of the 40–60-mM Na⁺ ions contributed by 20 mM nucleotides. The concentration of magnesium acetate used in these studies was 6.6–7.2 mM, just lower than the total dNTP concentration of 8 mM. Synthesis of long DNA molecules proceeded for 12–20 h, and the incubation could be continued for at least 40 h without detectable degradation of the product DNA.

The products of reverse transcriptase reactions were assayed for infectivity by the Ca₃(PO₄)₂ coprecipitation method of Graham and van der Eb^{10,11} as previously described^{12,13}. The total nucleic acid was extracted from an incubation mixture with sodium dodecyl sulphate, phenol, and chloroform, passed over a column of Sephadex G-50, and ethanol precipitated. In most experiments, virion RNA was not removed before transfection. After exposure to the nucleic acid, NIH/3T3 cells derived from NIH/Swiss mice were scored for successful infection using the syncytium-forming assay with an XC cell overlay as previously described^{12,14}.

Unincubated virions and virions incubated in suboptimal conditions for DNA synthesis were consistently devoid of infectious nucleic acid. After 3–4 h of incubation in the conditions described above, however, infectivity could be detected in the reaction product and increased thereafter for at least 12 h (Fig. 1).

Transfection yields complete virus

To determine whether the transfected cells forming syncytia with XC cells were producing complete virions, the culture fluids of NIH/3T3 cells transfected with endogenous reaction product were assayed for infectious virus. Titres of 10²–10³ PFU per 10 ml culture fluid were found within 3 d of transfection in every culture yielding even one or two infective centres by primary XC assay. After 15 d culture, the supernatants of transfected cells yielded titres of over 10⁶ PFU ml⁻¹. Mock-transfected cells always remained virus free. Therefore transfection with reverse transcriptase products resulted in the production of infectious virus.

The fact that virus spread efficiently through the transfected culture suggested that it was not an endogenous virus, since the only reported endogenous virus of NIH/Swiss mice is xenotropic, that is, incapable of infecting murine cells¹⁵. To confirm the origin of the transfection-derived virus, it was tested for the distinctive host range of the parent M-MuLV. M-MuLV grows equally well on NIH/3T3 (N-type) and BALB/3T3 (B-type) cells, but no known endogenous virus of mice can grow on both. When the transfection-derived virus and M-MuLV were titred on NIH/3T3 and BALB/3T3 cells, the ratio of the titre on N cells to the titre on B cells was 2.9 for M-MuLV and 2.4 for the transfection-derived virus. As controls, an N-tropic virus stock was shown to have a 100-fold preference for the N-type cells, while a B-tropic virus stock had a 10,000-fold preference for B-type cells. Thus the transfection-derived virus displayed the host range of the M-MuLV used in the reverse transcriptase reaction, and not of any known endogenous virus. Unless every infective centre resulted from recombination of M-MuLV fragments specifying host range with an endogenous viral genome, the product of incubated virions contained all the essential genetic information of M-MuLV.

Structure of infectious molecules

The biochemical nature of the infectious molecules was studied by subjecting them to various treatments (Table 1). The infectivity was unaffected by protease, and resistant to RNase at low ionic

Fig. 1 Synthesis of infectious DNA *in vitro*. Virions were incubated in an endogenous reaction mixture containing 320 c.p.m. pmol⁻¹ ³H-dCTP. At the indicated times, the nucleic acid was extracted from a sample, freed of unincorporated substrate, and used to transfect two plates of 1 × 10⁶ NIH/3T3 cells. The amount of DNA in each sample was determined by monitoring the radioactivity immediately before the addition of CaCl₂. Each point shows the total number of XC plaques obtained with a DNA sample corresponding to about 90 μg of virus protein. Δ, DNA recovered; ●, PFU.

strength, a treatment which will solubilise even RNA hybridised to DNA. Deoxyribonuclease completely abolished the infectivity. Therefore the infectivity must depend on DNA but not on a DNA-protein or DNA-RNA complex. The infectivity was not affected by heating to 68 °C in low salt to disrupt aggregates or by denaturation at 37 °C in 0.1 M NaOH. Complete resistance of the infectivity to alkaline denaturation was observed in the four independent DNA preparations tested. The implications of this result for the structure of the infectious molecules are discussed below.

Since the specific infectivity of the total endogenous reaction product was at least three orders of magnitude lower than that of purified proviral DNA (ref. 12) relatively high concentrations of reverse transcriptase product had to be applied to the cells. Thus it was conceivable that much or most of the infectivity was due to complementation among different partial transcripts. Two different DNA preparations of similar specific infectivity were used to study the dose-response of the transfection. In both cases (Fig. 2)

Table 1 Infectivity of reverse transcriptase product after different treatments

Treatment	XC plaques	DNA (μg)	PFU μg ⁻¹
None	54	0.32	167
68 °C	43	0.31	137
0.1 M NaOH	45	0.29	154
Proteinase K	45	0.25	178
RNase	15	0.14	105
DNase	0	<0.02	—

Virus at 1.6 mg ml⁻¹ was incubated in an endogenous reaction containing 15 mM Mg acetate, 60 mM NaCl, and each dNTP at 5 mM. Incubation was for 7 h at 37 °C. After deproteinisation and gel filtration, six portions were ethanol precipitated. The control was used for transfection in 1 ml of HEPES-buffered saline in standard conditions. One sample was dissolved in 50 μl of 2 mM Tris-HCl, pH 8, 2.2 mM EDTA, and incubated for 5 min at 68 °C before addition of HEPES-buffered saline. One sample was dissolved in 20 μl 0.1 M NaOH and incubated for 15 min at 37 °C, then chilled, diluted with HEPES-buffered saline, and adjusted to pH 7.05 with acetic acid. RNase digestion was for 30 min at 37 °C with 50 μg ml⁻³ pancreatic RNase in 2 mM Tris-HCl pH 7.5, 1 mM EDTA. DNase treatment was for 30 min at 37 °C with 20 μg ml⁻¹ DNase in 2 mM Tris-HCl, pH 7.5, 10 mM MgCl₂. Nuclease-treated samples anti control were subsequently treated with 1 mg ml⁻¹ proteinase K for 10 min at 37 °C and extracted twice with chloroform iso-myl alcohol. They were ethanol precipitated again before transfection.

Fig. 2 Dose-response of transfection with endogenous reaction product. ^3H -DNA with a specific activity of $42,400 \text{ c.p.m. } \mu\text{g}^{-1}$ was synthesised from two different harvests of M-MuLV, as described in the legend to Fig. 1. Incubation was for 13.7 h at 40°C . One DNA preparation (\bullet) was subjected to serial threefold dilutions, and the other (\circ) was used in twofold dilutions. Both sets of samples were then ethanol precipitated and used to transfect duplicate plates of cells. The concentration of DNA in each dilution was ascertained by measuring the radioactivity in an aliquot. The broken lines represent the theoretical curves expected for one-hit and two-hit processes giving 500 plaques per $2 \mu\text{g}$ DNA.

the titration showed single-hit kinetics. On a double-logarithmic plot, the slopes of the lines giving the best least-squares fit through each set of points were 1.09 ± 0.10 and 1.22 ± 0.10 . Thus it is most likely that all the genetic information of M-MuLV was carried in individual molecules or molecular complexes resulting from reverse transcription.

Effects of actinomycin D

The alkali resistance of the infectivity, noted in Table 1, suggested that duplex structure might not be required. If single strands of DNA were infectious, then actinomycin D, which selectively blocks synthesis of the second (positive) strand, might be expected to allow infectious molecules to be made. Pairs of DNA samples synthesised in parallel with and without the inhibitor were therefore tested for infectivity (Table 2). In each case, the sample made in the presence of the drug lacked detectable infectivity, whereas the parallel sample made in the absence of the drug was highly infectious. The difference was not due to persistence of small amounts of actinomycin D through the phenol extraction, which might inhibit transfection directly, because a sample made in the absence of the drug remained infectious after addition of $100 \mu\text{g ml}^{-1}$ actinomycin D followed by phenol extraction. Thus actinomycin D prevented the synthesis of infectious molecules.

DNA preparations made with or without actinomycin D were compared in an attempt to explain the difference in biological activity. After 12 h of synthesis, the DNA made in the absence of the drug consistently banded in isopycnic gradients of NaI as almost fully double stranded¹⁶. Actinomycin D, at $100 \mu\text{g ml}^{-1}$, completely suppressed the formation of double-stranded molecules, allowing only the synthesis of negative-strand DNA (not shown). This result is consistent with previous reports^{17,18}. Another difference was found, however, when the ^3H -labelled products of reactions with and without the drug were fractionated by electrophoresis through alkaline Agarose gels, and the DNA displayed either by staining with ethidium bromide (Fig. 3a) or by

fluorography of incorporated tritium (Fig. 3b). In completely denaturing conditions¹⁹, products of both reaction mixtures migrated as an array of species with molecular weights of up to 2.5×10^6 – 3.0×10^6 . The majority of the additional DNA made in the absence of actinomycin D was smaller than about 2×10^6 daltons. This size range is consistent with the size of the majority of positive-strand DNA found *in vivo*²⁰. As previously reported⁶, the longest molecules in each sample formed a discrete band (arrows in Fig. 3b). In the absence of the inhibitor, however, the most extensive transcripts were about 0.2×10^6 MW (600 nucleotides) larger than the largest species made in the presence of the drug (compare lanes 1 and 2, Fig. 3). Both species were capable of hybridising to ^{125}I -labelled virion RNA, and so both represented the first (negative) strand of DNA (F. Yoshimura & E. Rothenberg, unpublished). Thus actinomycin D apparently blocked the addition of about 600 nucleotides to the longest negative-strand polymerase products. The biological deficiency of DNA made in the presence of the drug could therefore be attributed to either of two effects: the absence of positive-strand DNA, or the incompleteness of the negative-strand transcripts.

Sedimentation of infectious molecules

To relate the infectivity more closely to the structure of the DNA, the total endogenous reaction product was fractionated by sedimentation through neutral and alkaline sucrose gradients and the fractions were assayed for infectivity. In the neutral sucrose gradient, the pattern of infectivity was comparable with that reported for the linear cytoplasmic viral DNA extracted from infected cells^{12,21}. A peak of infectivity was observed sedimenting at 18–20S, with no infectivity in material sedimenting more slowly than linear SV40 DNA (Fig. 4a). This is consistent with double-stranded linear molecules of full genome size, 8,000–9,000 nucleotides long. In contrast to viral DNA found *in vivo*¹², the endogenous reaction product contained a relatively high proportion of infectivity sedimenting rapidly from 20S to about 60S. These molecules might be DNA concatemers or DNA still associated with remnants of the 70S RNA complex. Since DNA synthesised in these conditions was almost completely double stranded, it was unlikely that any appreciable fraction of the rapidly-sedimenting infectious material might be single-stranded DNA of genome length.

If denatured endogenous reaction products were infectious, full infectivity should be retained by a sample fractionated on an alkaline sucrose gradient. This was not the case: in three separate attempts, only about 10% of the infectivity could be recovered from these gradients (Fig. 4b). Virtually no DNA was lost during

Table 2 Effect of actinomycin D on synthesis of infectious DNA

Sample synthesised with	DNA (μg)	PFU	PFU μg^{-1}
1 No actinomycin D	1.9	172	92
$100 \mu\text{g ml}^{-1}$ actinomycin D	0.57	0	<1.8
2 No actinomycin D	0.90	92	102
$100 \mu\text{g ml}^{-1}$ actinomycin D	0.35	0	<2.9
3 No actinomycin D	0.78	309	396
$100 \mu\text{g ml}^{-1}$ actinomycin D	0.28	0	<3.8
4 No actinomycin D	1.5	558	365
No actinomycin D; $100 \mu\text{g ml}^{-1}$ actinomycin D added after incubation	1.5	338	224

Pairs of DNA samples labelled with ^3H -dCTP were synthesised in parallel with or without $100 \mu\text{g ml}^{-1}$ actinomycin D. Different virus preparations were used for different experiments, in incubations of 19 h (experiment 1) or 16 h (experiments 2 and 3) at 40°C . The DNA sample used in experiment 4 was one of the samples described in the legend to Fig. 2. Each sample was used to transfect duplicate plates of NIH/3T3 cells, monitoring the input of DNA by radioactivity. In experiment 4, actinomycin D was added to a sample of the purified DNA preparation to a final concentration of $100 \mu\text{g ml}^{-1}$; the sample then underwent two extractions with phenol and one with chloroform before ethanol precipitation. The control sample in experiment 4 was precipitated directly without extraction.

Fig. 3 Effect of actinomycin D on size of reverse transcriptase products. ^3H -labelled DNA samples synthesised in the absence and presence of actinomycin D (a gift of Merck, Sharp and Dohme), as described in the legend to Table 2 (experiment 3), were analysed by electrophoresis on a slab gel of 1% Agarose in the denaturing conditions described by McDonnell *et al.*¹⁹. The gel was cast in 30 mM NaCl, 2 mM EDTA on a plug of 2% Agarose in the same buffer; the samples were applied in 2 mM Tris-HCl, pH 7.5 1 mM EDTA for 13 h at 25 V. The gel was stained with $0.5 \mu\text{g ml}^{-1}$ ethidium bromide²² and photographed during ultraviolet excitation (a). The same gel was treated for fluorography²³ and exposed to film for 6 d at -70°C . Lane 1: DNA synthesised in the absence of the drug. Lane 2: DNA synthesised in the presence of $100 \mu\text{g ml}^{-1}$ actinomycin D. The single-strand molecular weights ($\times 10^{-6}$) of the marker DNAs, adenovirus type 2 cleaved with *Bam*HI endonuclease and phage P22 cleaved with *Eco*RI endonuclease, were as given by H. Delius, R. Greene, and C. Mulder (unpublished), and E. N. Jackson, H. I. Miller, and M. L. Adams (submitted for publication), respectively. Two additional single-strand fragments in the P22 digest were previously reported⁶.

the fractionation, and control samples not submitted to fractionation retained their infectivity. The longest DNA molecules made *in vitro* had previously been shown to resediment on alkaline sucrose gradients without evidence of degradation⁶ so that it seemed unlikely that breakage was responsible for the loss of infectivity. Furthermore, the remaining biological activity sedimented not as full-length transcripts, which should be in fractions 7 and 8 (Fig. 4b), but as molecules of only 4,000–5,000 nucleotides (fractions 9–10), between the full-length single strands and the bulk of the DNA (fractions 11–12, Fig. 4b). Similarly, when a sample identical to that shown in Fig. 4a was denatured in alkali before fractionation on a neutral sucrose gradient, once again only 10% of the infectivity was recovered. As observed with the alkaline sucrose gradient fractionation, the residual infectivity in these neutral sucrose gradients was found in material sedimenting more rapidly than the bulk of the DNA but more slowly than full-length single strands (not shown).

These results present two striking paradoxes: first, that infectious molecules should sediment in alkali similarly to DNA of only half genome length, and second, that DNA which quantitatively retained its infectivity through complete alkaline denaturation should lose biological activity if fractionated by size before transfection.

Discussion

The drastic loss of infectivity in these experiments suggested that size fractionation of the denatured DNA could be separating components which were jointly required for biological activity. The infectivity recovered from the alkaline sucrose gradient could

then result from reassociation of these components. The nature of these cooperating components is suggested by the observation, noted above, that the genome-length transcripts seem to represent the negative strand, whereas the positive strand molecules seem to be distinctly shorter. Size fractionation of the denatured reverse transcriptase products would thus result in the separation of all positive strand DNA from the only molecules which were genetically complete. We therefore believe it most likely that for a molecule to be infectious, the cooperation of a full-length negative strand and some shorter positive-strand DNA is required. On this interpretation, the small peak of infectivity in Fig. 4b would represent the limited overlap of the peaks of full-length negative strands and incomplete positive strands, and the quantitative resistance of the infectivity to simple alkaline denaturation (Table 1) would be an artefact of rapid reassociation. The positive-strand

Fig. 4 Sucrose gradient sedimentation of reverse transcriptase product. a, Total nucleic acid from an endogenous reaction was centrifuged through a 4.8-ml 15–30% sucrose gradient in 0.1 M NaCl, 0.02 M Tris-HCl, pH 8.3, 0.002 M EDTA, for 2 h at 48,000 r.p.m., 4°C , in the SW 50.1 rotor. The 16S marker, ^{14}C -labelled SV40 DNA cleaved with *Eco*RI endonuclease, was centrifuged in a parallel bucket. Fractions of 0.32 ml were collected from the bottom and the ^3H -labelled DNA was detected by liquid scintillation counting of 30 μl aliquots (●). Each fraction was used to transfect a single plate of NIH/3T3 cells (○). b, A sample of one of the DNA preparations described in the legend to Fig. 2 was centrifuged through a 5-ml gradient of 5–20% sucrose in 0.3 M NaOH, 0.7 M NaCl, 0.005 M EDTA, 0.1% sarkosyl, for 4.5 h at 49,000 r.p.m., 4°C , in the SW 50.1 rotor. Fractions of 0.26 ml were collected from the bottom, neutralised with an equal volume of 100 mM Tris, 0.3 M acetic acid, and used to transfect single plates of cells as above (○, PFU). A portion of the unfractionated DNA was transfected in parallel, yielding a value for the input infectivity of 150 PFU. The DNA was detected by counting 50 μl portions of the neutralised fractions before ethanol precipitation (●, ^3H). The marker was as described in (a). In both experiments the recovery of DNA after ethanol precipitation was greater than 80% in every fraction.

fragment might be necessary as a primer for cellular DNA polymerase to complete the proviral DNA duplex before integration.

This interpretation does not directly address the question of the unexpected size difference between the longest strands made in the presence and absence of actinomycin D. If the longest DNA made in the presence of the drug were in fact a complete transcript, then the extra sequences might be part of a self-complementary 'hairpin' structure initiating the positive strand. Alternatively, the additional sequences might represent a transcript of the 5'-proximal 600 nucleotides of the RNA template, untranscribed in the presence of the inhibitor.

In summary, we have shown that detergent-disrupted virions of M-MuLV can synthesise DNA which is infectious. DNA made in the endogenous reverse transcriptase reaction can specify the synthesis of complete, infectious virus with the host range of the parent stock; this genetic information is probably carried on individual duplex molecules and not provided by complementation among partial transcripts. Thus it is likely that the virions contain all activities necessary for the synthesis of unintegrated proviral DNA. Reverse transcription in purified virions may accurately reflect the mechanism of synthesis of the viral DNA in infected cells.

A preliminary account of these findings was presented at the Cold Spring Harbor meeting on RNA tumour Viruses, May 30, 1976. We would like to thank Daniel Donoghue for thoughtful advice and valuable criticism throughout this work. This research

was supported by grants from the National Cancer Institute and the American Cancer Society and by a contract from the Virus Cancer Program of the National Cancer Institute. During part of this work, E.R. was supported by an NSF graduate fellowship. R.A.W. is a Cancer Research Scholar of the American Cancer Society, Massachusetts Division. D.B. is a Research Professor of the American Cancer Society.

Pulsar interpulses and other off-pulse emission

THE pulse emission from pulsars is usually confined to a window having a width of a few per cent of the pulsar period. Seven out of the 149 known pulsars, however, exhibit secondary pulses known as interpulses¹ which follow the relatively stronger main pulses by about half of the pulsar period. While it seems that only a few pulsars have observable interpulses, not all of the known pulsars have been carefully examined for this phenomenon. This is mainly because once a pulsar has been discovered, observers tend to concentrate on studies of the pulse window rather than the whole pulsar period. Consequently it would be statistically incorrect to compare the fraction of pulsars known to have interpulses with the fraction predicted by a proposed pulsar model. In order to check this possibility we conducted an interpulse search on the pulsars that are visible from Jodrell Bank. We report here the results of this search in which one new interpulse was discovered. These observations also revealed the presence of weak emission from regions other than the main pulse and interpulse windows in the cases of three pulsars.

The search took place between July 1975 and April 1976. Observations were made on approximately 100 pulsars at 327, 408 and 610 MHz and of about 50 of these pulsars at 151 and 240 MHz. For each pulsar the full period was observed for a total time of about 90 min. Dispersion removing techniques² were used to keep dispersion smearing comparable with the bin size of 1/400th of the pulsar period. At each frequency observations were made simultaneously, using two contiguous frequency bands of widths 2 MHz at 408 MHz and 610 MHz and 0.5 MHz, at the other frequencies. This enabled an interpulse to be distinguished from interference since the pulse arrival

times would be different in the two bands due to dispersion. The observation of an interpulse at several frequencies provided further checks on the validity of an identification.

Out of all the pulsars observed only PSR1822-09 revealed a previously unknown interpulse. The full period profile of this pulsar is shown in Fig. 1. The interpulse, whose intensity is ~10% of the main pulse, has been seen at 327, 408 and 610 MHz with approximately 170° of longitude separation from the main pulse (where 360° represents the whole pulsar period). Note that PSR1822-09 has several features in common with the Crab Nebula pulsar, PSR0531+21. Besides having interpulses both pulsars have a precursor to the main pulse and both have relatively large values of *P* (the period time derivative). Observations³ of PSR1822-09 indicate that this pulsar also emits pulsed γ rays like PSR0531+21. We suggest that there may be a causal connection between these phenomena.

Figure 1 also shows the profile of PSR0740-28 for which a new component has been detected at 240 MHz. This component has ~4% of the intensity of the main pulse and follows the main pulse by about 70° of longitude. The component is below the limit of detection at 327 MHz and is obscured by interstellar scattering at 151 MHz. The separation between this component and the main pulse is possibly too small to identify it as an interpulse and we regard it as part of the main pulse window which, therefore, has a width of about 70° longitude.

From the survey, therefore, it seems that interpulses are a property of only a few pulsars; of the 105 pulsars studied only four, PSR0531+21, PSR0950+08, PSR1822-09 and PSR1929+10, showed interpulses. Of the remaining pulsars with known radio interpulses, PSR0904+77, PSR0823+26 and PSR1055-52, two were too weak to be detected and one is not visible from Jodrell Bank. (The interpulse in the Vela pulsar, PSR0833-45, is only seen at optical and γ wavelengths). The pulsars with interpulses have, with one exception (PSR0904

+77), shorter than average periods and three of the six that have determined values of \dot{P} have very large values for this. These are thought to be characteristic of young pulsars⁴ which suggests that interpulses may also be a property of young neutron stars. This accords with theory since interpulses are generally thought to indicate that the observer is seeing the effects of both magnetic poles of the neutron star. This occurs when the magnetic axis is almost orthogonal to the rotation axis of the star and Jones⁵ has suggested that this may in fact be the case for the youngest pulsars. According to this model the axes begin to realign after $\sim 10^6$ yr and consequently interpulses should not be seen for the older pulsars. A completely opposite view of pulsar magnetic field alignment has been put forward by Flowers and Ruderman⁶. They also propose an alternative explanation of interpulses and our results may be understood in terms of either model.

Our observations also provided a second result: three pulsars exhibited low frequency emission with a wide longitudinal distribution. Figure 2 shows the full period profiles of these pulsars at several frequencies. This weak emission was confirmed by the presence of a time delay between its components in the two adjacent frequency bands caused by dispersion. Observations⁷⁻⁹ at other wavelengths have shown similar features to be present in other pulsars but greatly enhanced. From Fig. 2 we deduce that this emission has a steeper spectrum than the main pulse radiation. This fact and the wide distribution in longitude suggest that we are dealing with a different part of

Fig. 1 Integrated profiles of *a*, PSR 1822-09 and *b*, PSR 0740-28. The positions of newly discovered interpulse and pulse components are marked by arrows. The intensity scale is linear but in arbitrary units and the length of the vertical bar at the top right hand of each figure represents the r.m.s. noise of the observation and corresponds to the uncertainty of the position of the fitted baseline. The width of the vertical bar shows the time resolution.

Fig. 2. The integrated profiles of three pulsars exhibiting low frequency emission with a broad longitude distribution: *a*, PSR 0450-18; *b*, PSR 1541+09; *c*, PSR 1718-32. The extent of the emission is shown by delimiters.

the magnetosphere to that responsible for the main and interpulse emissions which tend to have similar widths and spectra.

Future observations of the polarisation of this phenomenon may help distinguish between these two emission regions and reveal further information about the magnetospheric structure of pulsars.

We thank Dr A. G. Lyne for much help and we acknowledge financial support from the SRC.

Observable gravitational effects on polarised radiation coming from near a black hole

THE effects of general relativity on the degree and plane of linear polarisation of X rays emitted by an accretion disk orbiting a black hole (such as Cyg X-1 might contain), were described in a previous letter¹ where we showed that the effects were large. Using a constant of motion along null geodesics in the Kerr metric, discovered by Penrose and Walker², we have since been able to calculate analytically polarisation rotations along any null ray. We present here more extensive results obtained by this method, for two different kinds of disk model and for different black hole angular momenta.

The alteration in observed polarisation properties from their Newtonian values³⁻⁶ is due to the strong bending of light rays coming from the accretion disk. The effects of gravitational redshifts and focusing are to strongly 'pick-out' some regions of the disk to contribute most to the observed properties. To show these effects we have made calculations for 'one'- and 'two'- temperature disk models^{7,8}. These models differ in that the former has a radial temperature gradient, whereas in the latter the inner region, closest to the black hole, has an essentially constant temperature. Although no completely satisfactory disk model exists, our calculations give some idea of the effects to be expected from more refined models.

Figure 1 shows the variation of the plane of polarisation, ϕ , as a function of observing energy for the one-temperature model, seen at a polar angle θ_0 of 41° . An observer above the disk ($\theta_0 < 90^\circ$) sees a clockwise rotation (not anticlockwise as

Fig. 1 Variation of plane of polarisation with energy for $\theta_0 = 41.1$ for the one-temperature model with A, $a/m = 0.9981$; B, $a/m = 0.9$; C, $a/m = 0$, where viscosity parameter, $\alpha = 0.1$; mass of black hole, $M = 9M_\odot$; mass accretion rate $= 7 \times 10^{17} \text{ g s}^{-1}$.

Fig. 2 Variation of linear polarisation with energy for the one-temperature model, with A, $a/m = 0.9981$; B, $a/m = 0.9$; C, $a/m = 0$. Same parameters as Fig. 1.

we stated previously¹). There is still an effect when the black hole is non-rotating ($a/m = 0$). This is because the disk itself is rotating, and the 'pick-out' still operates. Figure 2 shows the degree of polarisation for the same parameters.

The two-temperature model has an outer region with the same structure as the one-temperature model, but it becomes optically thin and hot at a transition radius of $r \lesssim 50$ gravitational radii. Above a threshold energy the radiation from the inner region is, locally, rotated by 90° compared with the optically thick case. So classically one would expect the polarisation vectors of photons coming from the outer and inner regions to be seen as perpendicular. When general-relativistic effects are included, and the 'pick-out' effect is integrated over the inner region, the observed plane of polarisation is not aligned with the projected polar axis, but has an additional jump, of the order of 10° , and the plane then has a constant direction at higher energies. Figure 3 shows the value of this jump in angle as a function of a/m , the angular momentum parameter.

Individual polarisation rotations can be determined analytically using the constant of motion found by Penrose and Walker. This is a complex number, constant along null geodesics in type (2, 2) space-times (the most astrophysically relevant of which is the Kerr metric). Its modulus is the constant of motion found by Carter⁹, and its argument contains the required information about polarisation rotations. The constant is

$$K_{pw} = \kappa^a f^b (l_a n_b) - m_l \bar{m}_b) \Psi_2^{-1/3}$$

where κ^a is the photon wavevector, f^b is the polarisation vector, $(l^a, n^a, m^a, \bar{m}^a)$ is the null tetrad based on the repeated principal null directions of the Kerr metric¹⁰, and Ψ_2 is a complex

function coming from the Weyl tensor. In Kerr we find (using Boyer-Lindquist coordinates¹¹)

$$K_{pw} = (\alpha - i\beta)(r - ia \cos \theta) = K_2 - K_1$$

where $\alpha = (\kappa^0 f^1 - \kappa^1 f^0) + a \sin^2 \theta (\kappa^1 f^3 - \kappa^3 f^1)$

and $\beta = (r^2 + a^2) \sin \theta (\kappa^3 f^2 - \kappa^2 f^3) - a \sin \theta (\kappa^0 f^2 - \kappa^2 f^0)$

Also we have $\mathbf{k} \cdot \mathbf{f} = 0$, and \mathbf{f} is only determined to within a multiple of \mathbf{k} (so we can choose $f^0 = 0$ at any fixed point).

For a given disk model we can evaluate α and β at the point where a null ray leaves the disk, from a knowledge of the initial polarisation vector. We then have to solve three linear equations for the three space-like components of \mathbf{f} at infinity. We find for orthonormal components

$$f^r(\infty) = 0, \quad f^\theta(\infty) = (SK_1 - TK_2)/(S^2 + T^2)$$

$$f^\Phi(\infty) = (-SK_2 - TK_1)/(S^2 + T^2)$$

where $S = (L_z/\sin \theta_0 - a \sin \theta_0)$

and $T = \text{sgn}(k^\theta) \times (Q - L_z^2 \cot^2 \theta_0 + a^2 \cos^2 \theta_0)^{1/2}$

here Q and L_z are constants of motion along the ray. In this way we obtain, after integration over the disk, the results shown in Fig. 1.

Fig. 3 General-relativistic jump for the two-temperature model, as a function of black hole angular momentum. Same parameters as Fig. 1.

Our previous numerical results for ϕ differ from the exact values by only about 1%.

We thank Roger Penrose for pointing out the analytic constant. Dennis Sciama for his help, and Drs T. Piran, G. Bath, J. Miller and Mr S. J. Rose and D. Pooler for helpful suggestions.

Quantum uncertainty in the final state of gravitational collapse

THE ratio of the action S to \hbar (Planck's constant/ 2π) determines whether the physical system in question is to be treated classically or quantum mechanically. In the area of classical physics the ratio S/\hbar is large compared with unity, and the governing equations are given by $\delta S = 0$. Quantum mechanics begins to be important when $S \lesssim \hbar$, and the definitive approach of classical physics is replaced by quantum uncertainty. We discuss here the behaviour of a physical system which is initially in the classical domain ($S \gg \hbar$) but whose later development may well take it into the region of quantum uncertainty. We consider a specific example of this—the gravitational collapse of a spherical dust ball. While classically such a dust ball ends up in a space-time singularity, the corresponding quantum mechanical result suggests a range of final states some of which are non-singular.

The explicit solution obtained here ignores pressures which have an important role in the gravitational equilibrium of stars. But classical relativity predicts that a space-time singularity develops in a body undergoing gravitational collapse in a fairly general and 'reasonable' set of physical conditions^{1,2}. Thus pressures satisfying 'physically reasonable' equations of state are not able to prevent this fate for those stars which become black holes towards the end of their evolution. For such stars S eventually becomes small enough for the above quantum considerations to become important. In these cases the above solution gives a qualitative indication of the probable types of final states.

The classical relativistic equations are derived from the variation of an action given by

$$S = \frac{c^4}{16\pi G} \int_V R(-g)^{1/2} d^4x - \sum_a \int m_a da \quad (1)$$

where c is the speed of light, G the gravitational constant, R the scalar curvature of space-time, g the determinant of the metric tensor g_{ik} . The second term of S is the action describing the behaviour of a system of particles labelled by a , with masses m_a . We may add other terms to S to include other possible physical interactions like electromagnetism. V is the 4-volume of space-time under consideration. In the classical approach, we may think of V as the region sandwiched between two chronologically ordered spacelike hypersurfaces Σ_1 and Σ_2 . The specification on Σ_1 of a 3-geometry $^{(3)}G_1$, and $^{(3)}G_2$, together with the field equations obtained from $\delta S = 0$ would lead to the determination of the 3-geometry $^{(3)}G_2$ on Σ_2 (see ref. 3).

The classical approach is a good one so long as $S \gg \hbar$, where $2\pi\hbar = h$ = Planck's constant. For most situations discussed in general relativity this condition is satisfied. But in the gravitational collapse of a compact object S may become small enough to be of the order \hbar close to the singularity. It therefore becomes necessary to examine this problem from the quantum mechanical point of view. Here we adopt the path integral approach.

In this approach, non-classical geometries, that is, those not satisfying $\delta S = 0$ are permitted and the above sandwich problem is rephrased thus. Given two 3-geometries, $^{(3)}G_1$ on Σ_1 and $^{(3)}G_2$ on Σ_2 what is the probability amplitude for the system with the given action (1) to go from one to the other? The answer may be expressed as a propagator $K[^{(3)}G_2, \Sigma_2; ^{(3)}G_1, \Sigma_1]$ which is obtained by the Feynman rule of sum over histories⁴.

In practice the execution of this project is extremely difficult and has not been done in the general situation. It is, however, possible to obtain an exact solution under a very limited form. Since this

form gives an insight into the gravitational collapse problem, it is described below in brief.

Following DeWitt⁵ we take into consideration only the conformal degrees of freedom. Suppose the classical solution of $\delta S = 0$ is described by a metric \bar{g}_{ik} . Consider non-classical solutions which are conformal to the classical one

$$g_{ik} = \Omega^2 \bar{g}_{ik} \quad (2)$$

where Ω is the conformal function. From (2) we get

$$\int_V R(-g)^{1/2} d^4x = \int_V (\Omega^2 \bar{R} - 6\Omega_i \Omega^i)(-\bar{g})^{1/2} d^4x + \text{surface term} \quad (3)$$

where on the right hand side the quantities refer to the classical metric. In the summing over histories we now have only the histories of Ω from Σ_1 to Σ_2 .

The problem is further simplified for the case of a collapsing homogeneous ball of dust in an otherwise empty space-time⁶. In terms of the comoving coordinates r ($\leq r_b$), θ , Φ , t , the classical solution is given by the line element

$$ds^2 = c^2 dt^2 - Q^2(t) \left[\frac{dr^2}{1 - \alpha r^2} + r^2(d\theta^2 + \sin^2\theta d\phi^2) \right] \quad (4)$$

in the interior of the ball. The scale factor $Q(t)$ is taken to be unity at the start of the collapse when the density was ρ_0 . The Einstein field equations $\delta S = 0$ give

$$\dot{Q}^2 = c^2 \alpha \left(\frac{1-Q}{Q} \right), \quad \alpha = \frac{8\pi G \rho_0}{3c^2} \quad (5)$$

The singularity ($Q = 0$) develops in a t -interval $\pi/(2c\alpha^{1/2})$. We will denote this instant by $t = 0$. As we are interested in the final stages of collapse, we will approximate the solution of (5) by

$$Q = \left(\frac{3c}{2} \alpha^{1/2} \right)^{2/3} T^2, \quad T = (-t)^{1/3} \quad (6)$$

Consider now the quantum fluctuations which preserve the symmetries of the problem. These are the conformal fluctuations for which Ω is a function of t only. We denote Σ_1 and Σ_2 by $t = t_1$, ($T = T_1$) and $t = t_2$, ($T = T_2$) respectively. Following the techniques of path integration⁴ it is possible to compute K exactly. The answer is best expressed in terms of the departure from the classical solution ($\Omega = 1$)

$$\Phi = \Omega - 1 \quad (7)$$

Given $\Phi = \Phi_1$ on Σ_1 and $\Phi = \Phi_2$ on Σ_2 we have

$$K(\Phi_2, T_2; \Phi_1, T_1) = \left(\frac{3iV\rho_0 c^2 T_1^2 T_2^2}{4\pi\hbar T_1 - T_2} \right)^{1/2} \times \\ \times \exp \left\{ \frac{3iV\rho_0 c^2}{4\hbar (T_1 - T_2)} [T_1^3 (T_1 - 2T_2) \Phi_1^2 + \right. \\ \left. + (T_2 - 2T_1) T_2^3 \Phi_2^2 + 2T_1^2 T_2^2 \Phi_1 \Phi_2] \right\} \quad (8)$$

where V is the coordinate volume of the ball.

This kernel has the reproducing property and its significance can be seen in the following way. Suppose at Σ_1 the state of the dust ball is described by a wave packet of dispersion Δ_1 in Φ_1

$$\Psi(\Phi_1, \Delta_1) = \left(\frac{1}{2\pi\Delta_1^2} \right)^{1/4} \exp \left(-\frac{\Phi_1^2}{4\Delta_1^2} \right) \quad (9)$$

where $\Delta_1 \ll 1$. Then at Σ_2 , with $|t_2| \ll |t_1|$, the state is described by a wave packet with a mean $\langle \Phi_2 \rangle = 0$ and a dispersion

$$\Delta_2 = \left(\frac{\hbar}{3V\rho_0 c^2 T_1 \Delta_1} \right) \left\{ 1 + \left(\frac{3V\rho_0 \Delta_1^2 c^2}{\hbar} \right)^2 T_1^6 \right\}^{1/2} T_2^{-2} \quad (10)$$

Thus, however small Δ_1 may be, equation (10) shows that Δ_2 diverges as $T_2 \rightarrow 0$, ($t_2 \rightarrow 0$). In other words, although the wave function at t_2 continues to have the classical solution ($\Phi_2 = 0$) as the mean, the spread around this solution gets progressively larger as the so-called classical singular epoch is approached: (10) effectively tells us where the quantum uncertainty begins to dominate. For a solar mass dust ball with $\rho_0 = 1 \text{ g cm}^{-3}$, the linear shrinkage must factor 10^{-43} before the quantum uncertainty takes over.

Although the smallness of this ratio indicates the range over which the classical theory is valid, the ultimate dominance of quantum uncertainty as $t \rightarrow 0$ seems inescapable.

This solution can also be used to discuss the early stages of a Friedmann universe. A few years ago Hoyle and Narlikar⁷ had suggested that the quantum fluctuations in a classical big bang model might produce models without particle horizons (which inhibit the transfer of information). It is interesting to note that the range of uncertainty indicated by Δ_2 permits such models.

I thank Professor J. A. Wheeler for discussions and for hospitality at the Center for Theoretical Physics, University of Texas at Austin. I also thank Professor Cecile DeWitt for discussions on path integrals, and the International Astronomical Union for a travel grant.

Origin of diffuse interstellar lines

SINCE their discovery over 40 years ago, the origin of the diffuse interstellar absorption lines has been a mystery although there have been many suggestions put forward. Developments in spectroscopy and astronomy have intensified rather than reduced the mystery. This letter takes into account some of these recent developments and suggests a rather definite (but unconfirmed) identification of the lines. Excellent surveys of the diffuse interstellar lines have been given by Herbig¹ and by Wu², so the many studies of these lines will not be mentioned again. For our purposes, it is sufficient to note that the strongest line which lies at 4,428 Å has a half width of 20 Å, and that 38 weaker lines of varying strengths and widths lie at longer wavelengths. The strength of the lines is strongly correlated with regions in space containing interstellar grains (particularly small grains) and there is strong evidence that all the lines arise from a single species or from closely related species. The only feature in the spectrum lying to the violet of 4,428 Å which seems to be related to the diffuse lines is a continuum in the 2,200 Å region but this must certainly involve much higher electronic states of the absorbing species.

The line widths of the diffuse lines are the unique characteristics which differentiate them from all identified interstellar lines. The line widths which vary between 1 and

100 cm^{-1} seem to preclude assigning the lines to transitions between discrete states of free atoms or molecules (which at the temperature of the interstellar region give bands narrower than the $40\text{--}100\text{ cm}^{-1}$ widths of most of the stronger lines). Many suggestions have been made regarding the origin of the lines. The line widths have been accounted for by assuming either that the absorbing species is pre-ionised or predissociated in its excited state, or that the absorbing species is on or in an interstellar grain where site inhomogeneities account for the line widths. The first of these hypotheses suffers because in spite of numerous studies of most of the abundant simple molecules and atoms, it has not been possible to identify the absorbing species. A second difficulty with the predissociation hypothesis is that each absorbed photon destroys the absorber and an efficient process must exist to restore the population. The second hypothesis also suffers because it has not been possible to identify the species which is responsible for the absorption. More important, considering the probable wide variation of sizes and compositions of the grains, it is difficult to conceive a system of grains and absorbers which will give the observed discrete set of lines with widths down to a few cm^{-1} and give series of lines extending only to the red of the strongest line at $4,428\text{ \AA}$. Danks and Lambert³ have shown that for a certain reasonable range of molecular moments of inertia, dipole moments and collision rates, the shapes of some of the diffuse lines can be fitted by band contours of heavy molecules. They do, however, have difficulty in fitting the wider lines and probably in accounting for the wide range of bandwidths.

Here I suggest that the lines are caused by the absorption of polyatomic molecules and that the line width is the result of radiationless internal conversion between stable states. Furthermore, I propose that the absorbing species are long chain carbon molecules, C_n where n may lie in the range 5–15. The direct evidence to support this is very meagre indeed but this suggestion seems to account for the observations without straining our present concepts of spectroscopy or astronomy.

A radiationless internal conversion results from an interaction between the levels of an excited electronic state and the higher vibrational levels of a lower state⁴. The process causes each rotational line of an electronic transition to be replaced by a band whose width depends on the interaction energy. This interaction energy varies greatly from one state to another and even from one vibrational level to another in the same electronic state. The band widths can be predicted only by very elaborate calculations but widths in the $1\text{--}100\text{ cm}^{-1}$ range are not unusual. For all but the most simple molecules, the band consists of such a high density of lines that it is for all practical purposes a continuum. Following the absorption of radiation in this band, the molecule will lose its excitation through a series of vibrational transitions. Thus, in molecules displaying this type of radiationless transition, diffuse bands are not accompanied by dissociation. It is worth noting that internal conversions are not rare phenomena but exist in most polyatomic molecules and are particularly important for the larger molecules.

Recently HC_3N (ref. 5), HC_5N (ref. 6), and HC_7N (H. W. Kroto *et al.*, submitted for publication) have been identified by radio observations of dense interstellar clouds. It seems most likely that this series will be extended to at least HC_9N once the spectrum of this molecule has been identified in the laboratory and it is reasonable to assume that long chain acetylenes, which have no dipole moment and thus cannot be observed, are more abundant than the observed cyanoacetylenes. How these long chains of carbon atoms are formed is unknown although their existence is firmly established. It can, therefore, be suggested that similar long chains of carbon atoms, either formed by the same process or released from

clouds, exist in the less dense interstellar regions. In the less dense regions, these chains may lose any hydrogen they had or acquire, by photodissociation and exist as pure carbon chains. We may further postulate that the shortest of the chains (C_2 , C_3 , C_4) are photodissociated but chains beyond a certain length can lose the energy absorbed in the form of radiation by the internal conversion process and are not readily photodissociated.

Pitzer and Clementi's⁷ calculations on the structures and electronic states of long chain carbon molecules agree with the experimentally observed high stability of these molecules, and indicate that the stability of chains with odd numbers of atoms is greater than those with even numbers. These calculations, which give only a qualitative picture of the absorption spectra, indicate that the smallest of the molecules should show strong absorption bands in the 2-eV ($6,000\text{-\AA}$) region with the corresponding absorption shifting to the red with increased chain length. Some alteration between chains with odd and even numbers of atoms is also expected in the position of the absorption spectrum with the odd tending to lie to shorter wavelengths. The simplest polyatomic carbon molecule, C_3 , is known to have a strong absorption band at $4,050\text{ \AA}$ (ref. 8) and there is evidence that C_4 has absorption bands in the $5,000\text{-\AA}$ region⁹. Therefore, if we examine the spectrum of a mixture of C_n molecules in which the abundance of C_n decreases as n increases and n has a certain lower limit such as 5, we should expect to find a series of bands extending to the red from a strong band in $4,000\text{--}5,000\text{-\AA}$ region.

The facts and postulates given above suggest that the strong $4,428\text{ \AA}$ band arises from the absorption of a C_n molecule where n is a number such as 5, 7 or 9. The absorption bands at longer wavelengths result from the various absorptions of longer chains. The known correlation between these absorption bands and small interstellar grains seems reasonable since at least some fraction of these grains may be nothing more than an aggregate of carbon chains. It is possible that some of the interstellar extinction in the ultraviolet, which is usually attributed to small interstellar grains, may be due to absorption into the higher electronic states of long chain carbon molecules.

The present hypothesis has the following merits: (1) It associates the observed absorption with very stable molecules which are composed of one of the most abundant elements and which have absorption bands in the region of the observed lines. (2) It accounts for the absence of lines at wavelengths shorter than the strong $4,428\text{-\AA}$ band. (3) It presents a process which could give the observed line widths and which does not involve the dissociation of a molecule with the absorption of each photon. (4) There is evidence that long chains of carbon atoms exist in at least some interstellar regions. (5) The association of the absorption bands with small interstellar grains seems natural.

The weakness of this suggestion lies in the lack of experimental evidence for the several postulated mechanisms. It has been assumed that radiationless transitions between stable states account for the line widths of the diffuse lines and may also protect the long chain molecules from photodissociation by ultraviolet light. It has been assumed that photodissociation destroys the short chain carbon molecules and removes other atoms, particularly hydrogen, from the chains and it has been assumed that the absorption bands of long chain carbon molecules lie at the positions of the observed diffuse lines. It may be possible to devise experimental test for some of these assumptions. Thompson, DeKock and Weltner¹⁰ have observed the infrared spectra of several long chain carbon molecules in argon matrices and there have been several mass spectrometry studies¹¹. Experimental studies of the electronic spectra of such carbon molecules should be possible in the near future.

I thank Drs G. Herzberg, J. M. MacLeod and T. Oka for their helpful comments.

Carbonaceous compounds in interstellar dust

SEVERAL infrared bands found recently in astronomical sources have not been assigned to specific substances in a convincing way (see refs 1–6). Resonance features in solids seem to be the most plausible emission and absorption mechanisms, but the features cannot be identified with known or suspected compounds in the interstellar dust grains such as silicates, water ice, silicon carbide, or graphite. We propose here a new substance, consisting of carbonaceous material, which may be responsible for some or all of the unidentified infrared features.

The infrared bands for which there are no positive identifications, or for which the identifications rest on the assignment of a single band, are listed in Table 1. The band at 3.3 μm has been studied in greatest detail. It is definitely broader than a single emission line and is unresolved at a spectral resolution of $\lambda/\Delta\lambda \sim 3,000$, ruling out the most attractive molecular candidates for the feature⁶. The apparent temperature independence of the feature and its presence in sources with widely differing physical conditions also makes a molecular origin seem doubtful. Here we interpret all of the features in Table 1 as solid resonance bands.

References to the other emission bands are given in Table 1. Less than ten sources containing these features have been observed so correlations among them are not yet firmly established. It seems that the presence of the 3.3- μm band and the 11.3- μm bands is not correlated, but the presence of the 3.4- μm and 11.3- μm bands might be⁶. Emission features at 6.2 μm and 7.7 μm were discovered by Russell *et al.*⁵ in the spectrum of the planetary nebula, NGC 7027. Observations at these wavelengths are just beginning to become available, and the sparsity of sources at this time is merely an observational effect. We have also listed the band at 11.3 μm as 'unidentified' despite previous suggestions of a carbonate origin, since subsequent observations did not reveal expected carbonate features

at 7 μm and between 28 and 35 μm (refs 1, 4). Therefore this identification must still be regarded as provisional.

Strong emission near 3.3 μm is highly suggestive of a substance incorporating carbon–hydrogen bonding since this is the well known wavelength of the fundamental C–H stretching vibration. Absorption bands between 3 and 3.5 μm are observed in carbon stars and some of these have recently been identified as HCN and C_2H_2 by high-resolution spectroscopy⁷. The existence of organic molecules which may participate in particle formation near carbon-rich objects is therefore well established. It is also plausible that in some cases the C–H bond is associated with a solid particle. The C–H could, for example, be attached to a matrix such as the observed silicate particles or the connected graphite grains. It is unlikely, however, that this is the case for all the sources since silicate emission or absorption does not necessarily accompany the unidentified bands. A more likely configuration would be a particle composed largely or entirely of carbonaceous material in which the C–H bonds are an ubiquitous component in an assemblage of organic molecules. Theoretical studies indicate that in a carbon-rich atmosphere, molecules such as C_2H_2 would condense to form a graphite-like substance or carbon particles which would contain at least a small admixture of C–H bonded material^{8,9}.

Grains formed in stellar atmospheres and expelled into a circumstellar environment, planetary nebula, or the interstellar medium would have a complex nucleation and growth history as well as a complex history of interaction with radiation and particles. While the resulting composition and structure of such grains is very uncertain, it seems plausible that they would be composed of a mixture of a large number of compounds reflecting the many chemical and physical processes to which the material has been subjected. For grains forming in a carbon-rich environment, one would then expect an ill-defined substance of high-molecular weight compounds with polymer or tar-like properties. Note, however, that the 3.3- μm band should be present in almost all organic compounds or combinations of them which condense to form solid particles.

The material we propose would resemble the high molecular weight organic compounds found in the carbonaceous chondrites. The major organic component in carbonaceous chondrites is a poorly defined substance which is apparently difficult to study in detail. The material is often called a 'polymer', but it is in fact not made of repeating monomers and seems to be an agglomeration of various units arranged in complicated ways¹⁰. This polymer-type material makes up 90% to 95% of the organic matter in meteorites. The hydrocarbons and amino acids in the chondrites are included in the soluble 5–10% of the organic matter.

There may be further similarities with organic material synthesised in conditions resembling planetary atmospheres. Methane and ammonia, have been subjected to electrical discharges¹¹, ultraviolet radiation¹², and proton irradiation¹³. In all cases high molecular weight, polymer-like solid material is formed. Khare and Sagan pointed out the similarities between the synthesised material and the organic compounds in carbonaceous chondrites¹². This material may, however, differ in substantial ways from condensation products in stellar atmospheres where conditions do not resemble those in the experiments or in the solar nebula. In this case, the present comparison is quite qualitative and based on the assumption, suggested by the arguments above, that similar carbonaceous material might form in disparate environments. On the other hand, circumstellar shells surrounding protostars are also likely formation sites for interstellar grains¹⁴. Grains formed there might resemble the carbonaceous meteoritic material quite closely.

The infrared spectra of some of these compounds are shown in Fig. 1 which includes spectra typical of the

meteoritic and synthetic materials. This comparison is subject to numerous uncertainties due to differences in sample preparation in the experiments. Particularly significant is the effect of the solvents on the material and that different extracts of the materials were measured. Nevertheless the spectra provide a qualitative comparison of the infrared properties of some of the organic compounds which form in the rather different conditions used in the experiments, and which may have analogues in the interstellar dust.

All of the spectra contain the expected strong absorption near 3.3 μm . The materials tend to be transparent between 3.6 and 5.7 μm and have a strong band located somewhere between 5.8 and 6.1 μm . This is identified as the vibration of C=C (ref. 11). Since this bonding would also be expected to be common in carbonaceous grains, we suggest that the grain feature at 6.2 μm (Table 1) is a C=C vibration. There is a discrepancy in band position between the astronomical spectra and the spectra of Fig. 1 of 0.1–0.5 μm which would have to be explained by a shift between the solid and dissolved material or perhaps by particle size and shape effects. Band displacements of a few tenths of microns are frequently observed in particle spectra¹⁴.

The spectra between 6.5 and 15 μm are different from each other and from the interstellar emitter. There seem to be real differences between the synthetic and chondritic materials. In the spectrum of Russell *et al.*⁵, the 7.7- μm emission seems to extend from 7.5 to 8.5 μm . While there is an overlap with an absorption probably due to C–O vibration between 8 and 9 μm , this is not a very convincing similarity. No strong feature near 11.3 μm occurs in the laboratory spectra. Either the 11.3- μm band is not due to carbonaceous material or is it due to a polymer somewhat different from those shown in Fig. 1. In this picture, however, it has a different molecular origin than the 3.3- μm feature. Unfortunately, the nature of the absorptions in this wavelength region complicates inferences derived from the spectra. Bands near 11.3 μm do occur in some organic compounds, for example the methyl group –CH₃ has an absorption at this wavelength. The 8–14- μm region is characterised by many overlapping bands of organic molecules often not readily assignable to specific fundamentals. Conversely, the patterns are complex enough to characterise molecules as a whole. If the identification

of the fundamentals suggested above proves correct, bands in the 8–14- μm region could provide more detailed information on the particle composition.

The carbonaceous material would probably be strongly absorbing in the visible or ultraviolet. Small particles of this material would be heated efficiently, possibly accounting for the high temperatures required to account for the emission bands in a nebula like NGC7027 (ref. 2). In regions where different solids occur (as distinct particles), temperatures would depend on the individual particle compositions through the emissivities and absorptivities. Small carbonaceous particles with strong ultraviolet absorption would reach elevated temperatures if their infrared emissivity is not too high. This could explain why the unknown features always seem to be in emission even when the silicates are in absorption.

The material proposed here is related in some ways to the graphite-like material which has long been suspected as a possible grain constituent. Unlike some previous suggestions, the carbonaceous particles would not have to meet stringent requirements on size, shape, or purity, at least to give the degree of agreement with the infrared observations discussed above. There seem to be similarities in the grains and in carbonaceous chondrites¹⁶. Further laboratory and observational work, especially in the 5–14- μm wavelength region, may show whether a second meteoritic material, the organic polymer-like material in carbonaceous chondrites, also has an analogue in the interstellar dust.

I thank J. Bregman for pointing out that the methyl group has an 11.3- μm absorption and for useful comments.

Lateral variation of phenocryst assemblages in volcanic rocks of the Japanese islands

To understand the origin of calc-alkaline rocks and island arc volcanism, knowledge of the lateral variation of the petrological characters of volcanic rocks is essential. The lateral variation of chemical compositions of volcanic rocks has been investigated by several authors¹⁻⁴ and correlated to the depth of the Benioff zone. The east volcanic zone of Japanese Islands, which contains about 140 discrete Quaternary volcanoes, is the most extensively studied volcanic zone in the world. I have examined the petrological data of these volcanoes, particularly with respect to the phenocryst assemblages in volcanic rocks and their changes during the history of respective volcanoes. The references have been mostly taken from 200 papers compiled by Isshiki *et al.*⁵

The volcanoes are classified into three groups on the basis of the presence or absence of hornblende and biotite phenocrysts in essential materials: (1) those without biotite and hornblende phenocrysts in any of the lavas or pyroclastics; 2) those with hornblende phenocrysts but without biotite phenocryst at least in one lava flow or pyroclastic rock; and (3) those with biotite phenocrysts at least in one lava or pyroclastic rock. The distribution of the volcanoes of these three groups is shown in Fig. 1.

Volcanic rocks containing biotite phenocrysts were erupted only in the western part of the volcanic zone, whereas those which do not contain any hydrous mineral phenocrysts were erupted in the eastern part of the volcanic zone. Volcanoes in a belt situated between the above two belts erupted rocks containing only hornblende as hydrous mineral phenocryst.

Phenocrysts such as pyroxene, hornblende, and biotite are considered to be precipitated in a magma reservoir or

during the ascent of magma. The lateral variation outlined above may be due to the lateral change in physicochemical conditions of magma reservoirs across the volcanic zone. It may also be due to a lateral variation in the chemical composition of the original magmas, for example, their alkali contents—especially the K₂O contents³ and possibly to the variation of H₂O contents in the original magma which may increase westwards across the volcanic zone.

I thank Professor I. Kushiro and Dr R. H. Grapes for their comments and criticisms.

Rare earth element mobility and geochemical characterisation of spilite rocks

HELLMAN & Henderson¹ have demonstrated the enrichment of the rare earth elements (REE) in the lower spilite portion of the Bhoiwada lava profile relative to the fresh tholeiitic flow top. The remarkable feature of the REE distribution in the spilites was the absolute enrichment of all the elements and not only the light REE, as occasionally seen in oceanic basalts due to submarine weathering². Thus the enhanced spilite REE distribution resembles either alkali basalt or tholeiitic differentiation products rather than tholeiitic basalt. As stated¹, the high degree of REE mobility suggests that these elements must be used with caution in determining the initial magma type or volcanic environment of ancient spilite rocks.

At face value the REE distribution in the spilites is very similar to that exhibited by the more alkaline units of the Deccan basalts^{3,4}. This feature suggests the possibility that the Bhoiwada profile may not be a single flow unit at all and the fresh tholeiitic 'top' may be a different unit to the more 'alkaline' spilite base. Although the section is described as gradational^{5,6}, there are primary textural differences (pillowed/massive; ophitic nature; vesicularity and so on) between tholeiite and spilite, and the contact seems sharp (see photomicrographs and photograph in refs 5 and 6). If the sub-aqueous (flow 'base')-sub-aerial (flow 'top') origin postulated for the flow⁵ is correct, then it lacks some of the features described for such lava flows^{7,8} and does not adequately explain why spilite-silicification should have stopped abruptly at the water-air interface. Also the considerable REE distribution gap (Fig. 2a of ref. 1) between tholeiite and spilite might lend support to the differences in the two zones, especially as there is no apparent gradational increase in normalised REE patterns with progressive spilite-silicification. This is particularly noticeable in the sudden jump of the La/Yb ratio¹ from tholeiite to spilite and also the chemical similarity between the spilite and the (separate) basal pillow lava unit.

Irrespective of whether the profile represents a single unit or not, however, independent criteria are required to characterise the spilite and compare it with the fresh tholeiite. A variety of geochemical (and mineralogical) parameters, which will give the same characterisation, are necessary to determine the nature of ancient altered volcanics. Vallance^{6,9} has advocated the use of relict pyroxenes to determine the magma type of spilite rocks. In the case considered here, the pyroxenes in both tholeiite and spilite are low-Ca augites of tholeiitic character and are similar in composition⁶. Apart from the REE, other relatively 'immobile elements', such as Ti, P, Zr, Y and Nb, have been used to determine magma type^{10,11} and again demonstrates the tholeiitic nature of

Fig. 1 Distribution of Quaternary volcanoes in Hokkaido and northern Honshu. ●, Volcanoes without biotite and hornblende phenocrysts in any of the lavas or pyroclastics; ○ those with hornblende phenocrysts but without biotite phenocryst at least in one lava flow or pyroclastics; open circles represent those with biotite phenocrysts at least in one lava or pyroclastics.

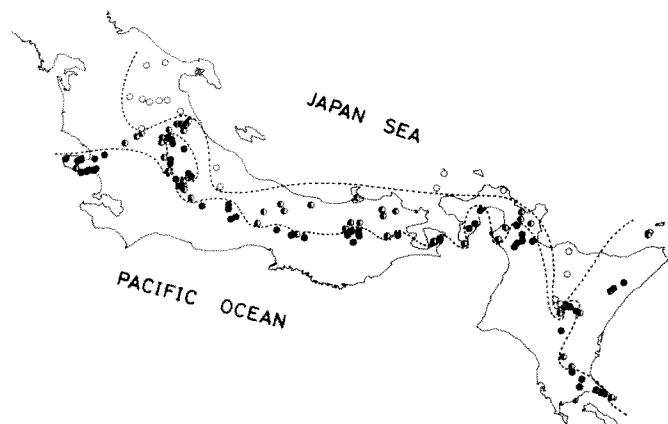

Table 1 Variation in chemical parameters from the Bhoiwada profile^{1,6}

Samples	I	Tholeiite	II	III	Spilite	IV	V (core)	Basal pillow unit V (rim)

Heavy	0.65		1.07	0.66		0.62		

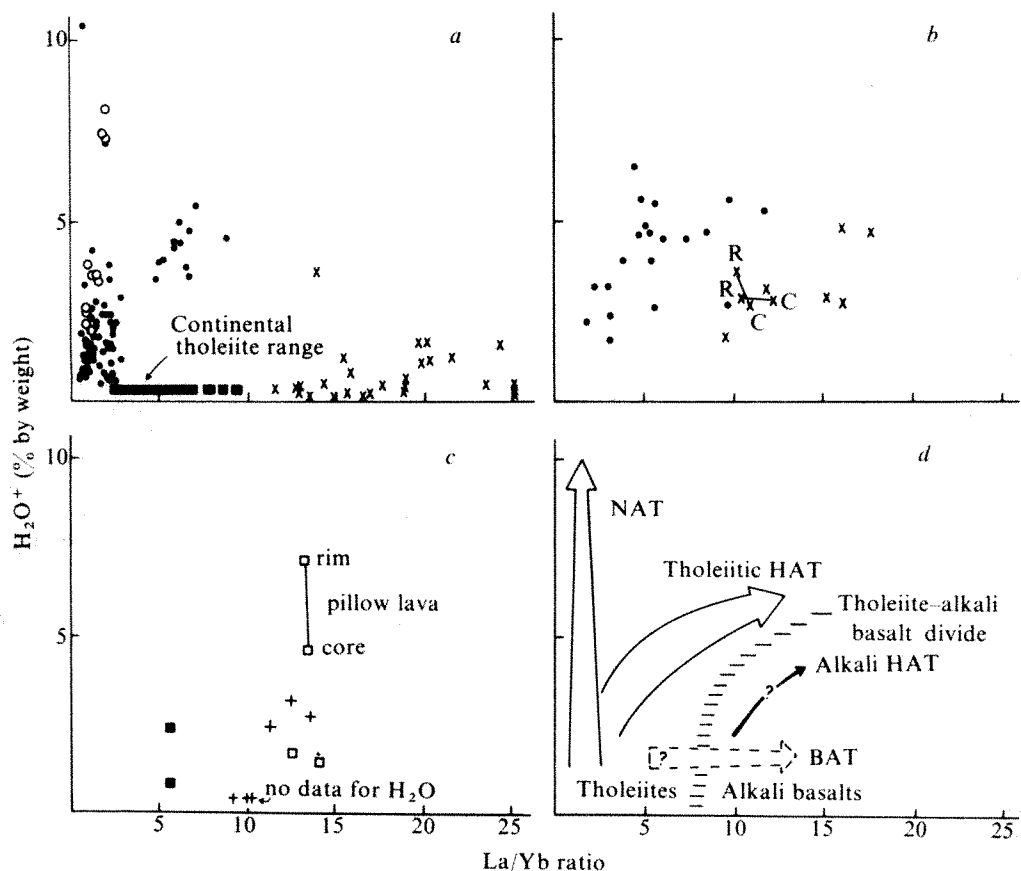

the spilite on the basis of the TiO₂-Zr/P₂O₅ diagram (Fig. 3 of ref. 12). But, there are differences (as well as clear similarities) between the rock units in terms of immobile element ratios (Table 1). Note in particular the more fractionated character of sample II⁶ (sample 2 of ref. 1) relative to sample I (sample 1) as shown by the higher Zr/TiO₂ ratio (see refs 13 and 14 for usage of this ratio). This is substantiated by the higher Σ Fe/Mg ratio of the separated heavy pyroxene fraction from sample II, although not apparently by the lighter fraction (Table 1). The spilites have similar Zr/TiO₂ ratios to the freshest tholeiite (sample I) and thus exhibit a similar degree of basaltic differentiation.

This example from the Bhoiwada profile illustrates the use of variable discriminatory parameters applied to spilitic rocks (compare ref. 13), but is at variance with the REE 'alkaline' designation. But, before any spilite with apparent 'alkali basalt' characteristics is dismissed as an REE-enriched tholeiite, we need first, to check the designation against other geochemical and mineralogical criteria (as above) and second, to test the degree of REE mobility against some alteration parameter, such as H₂O⁺, in each situation. With pillow lavas it is also customary to compare the rim and core portions to determine the zone of possible enrichment.

I now briefly examine the effect of progressive hydration (as H₂O⁺) on the REE in relatively modern basalts and compare the distribution and fractionation (as the La/Yb ratio) with spilites from the Variscan of western Europe. Within this framework the Bhoiwada basalt-spilite fractionation pattern can be compared. It must be emphasised that H₂O⁺ is only one of several possible alteration parameters¹⁵, although in view of the development of hydrous low-grade assemblages in spilites and also hydrated glass in modern sea-floor basalts, it seems the most appropriate (compare ref. 13).

Figure 1a is a plot of relatively recent tholeiitic and alkali basalts mainly from the oceanic environment and shows their separation on the basis of the La/Yb ratio (representing light to heavy REE fractionation). The relative position of continental tholeiites is indicated schematically, due to the general lack of H₂O⁺ determinations and is based on data from various localities^{4,16,17}. The common La/Yb range for continental tholeiites is about 2-7 (with a few values up to ~10), whereas continental and oceanic alkali basalts show a much wider range with La/Yb ~11-40 (Fig. 1a and ref. 17). Associated oceanic island tholeiites and alkali basalts from Hawaii¹⁸ show La/Yb ranges of 3.9-6.8

Fig. 1 Variation of La/Yb ratio with hydration in various basaltic and spilitic rocks. *a*, Fresh and altered tholeiites and alkali basalts, mainly from the modern oceanic environment (data from refs 2, 4, 18-20, 23-33). \times , Alkali basalts; \bullet , tholeiitic basalts; \circ , spilites/greenstones. *b*, Variscan spilites from western Europe (data from refs 21, 22 and unpublished). \bullet , Tholeiitic spilites; \times , alkali basalt spilites. R = rim; C = core. *c*, Bhoiwada profile tholeiites and spilites (data from refs 1, 6) compared with some Deccan basalts (data from refs 3, 4 and 16). \blacksquare , Fresh tholeiite; \square , spilitic rocks; $+$, Deccan basalts. *d*, Summary diagram showing development of various trends for La/Yb. NAT, no alteration trend; HAT, hydrous alteration trend; BAT, Bhoiwada alteration trend.

and 7.8–15.6 respectively and coupled with the above data provide an approximate magma type divide at La/Yb of ~ 7 –8.

The ocean floor/ridge tholeiites in Fig. 1a exhibit two trends with increasing hydration—(1) increasing La/Yb in samples with $H_2O^+ > 3\%$ by weight and (2), no change in La/Yb, irrespective of H_2O^+ content, even up to very high values (10% by weight). Both of these features are seen in basalts that have suffered low-temperature alteration with palagonitisation of glass and developed smectitic clays, carbonate, Fe oxides and rare zeolites. Also higher temperature alteration, exhibited by recent ocean floor rocks and generally termed greenstones or spilites (for example refs 19 and 20), show no significant change in the La/Yb ratio with progressive hydration. Unfortunately there is a lack of analyses of sufficiently altered alkali basalts to show any similar trends, although within any one volcanic province the variation is minimal (up to 2% H_2O^+ by weight) in rocks of similar basaltic composition.

Figure 1b shows the variation of the La/Yb ratio with hydration in various Upper Palaeozoic spilites from western Europe. This includes REE data from north-western Germany^{21,22}, south-western England, Brittany and southern Portugal (unpublished data by PAF). The south-western England data includes both intrusive sills and pillow lavas that have been designated as tholeiites or alkali basalts on the basis of the distribution of other 'immobile' elements (refs 11, 13 and Table 2). Note that the La/Yb ratio increases with progressive hydration

enrichment²⁴, but not to the degree as illustrated by the Bhoiwada spilite. As seen in Table 2, the pillow rims are enriched relative to their cores, with the enrichment in both cases being almost entirely due to Ce and to a lesser extent Sm.

Figure 1c shows the Bhoiwada lava data^{1,6} and various Deccan basalts^{3,4,16}, which characterised by high La/Yb ratios suggest an 'alkaline' character for these particular samples. Compared with the alteration trends derived from Fig. 1a and b, the development of the Bhoiwada spilite is unusual in showing a marked La/Yb enrichment without any attendant H_2O^+ increase. Also, if the basal pillow lava unit was originally tholeiitic, the whole pillow has been REE enriched such that the rim and core have developed similar La/Yb ratios. The pillow lava, due to its high H_2O^+ content, could fall on the end of the altered basalt/spilite trend of Fig. 1a and b. Certainly the form of variation exhibited by the Bhoiwada profile is different from that seen elsewhere and may define another (abnormal?) trend. It is difficult to see what this difference may be due to, as the Bhoiwada alteration products (chlorite, albite, prehnite, laumontite⁵) are not markedly different from the mineralogy of some ocean floor spilites. Adsorption of La (and other REE?) by layer silicates has been suggested¹ as a factor in determining REE distribution patterns, although equally chloritic spilites (or clay-rich altered basalts) do not show such a high degree of enrichment in the marine environment.

In conclusion, it seems that the REE can be fractionated during alteration, although the trends of alteration in such cases can still

Table 2 Variation of immobile element ratios and chemical alteration criteria in associated portions of massive and pillowed spilites from south-western England

(especially in samples with $H_2O^+ > 3\%$ by weight) in a similar manner to one of the trends exhibited by the altered oceanic floor tholeiites of Fig. 1a. Although the La/Yb ratio in the altered tholeiites increases towards more alkaline values (~ 10) this only takes place at a relatively high level of alteration (5–6% H_2O^+ by weight) and would only be confused with alkali basalts if their La/Yb ratio remained constant at the same level of alteration. The alkali basalt designated spilites (largely from south-western England) have typical alkaline La/Yb ratios and are separate, in terms of alteration trends, from the tholeiitic spilites. In the alkali basalt pillow lavas the La/Yb ratio marginally decreases from core to rim (Table 2). de Paape *et al.*²³ have also demonstrated the lack of variation in pillow lava segments with core and glassy crust La/Yb ratios being essentially the same, although the H_2O^+ content is considerably different.

Together with variation in the ocean floor basalts, the plotted spilite data suggests variation of the La/Yb ratio with alteration, although the trends of variation seem to still allow spilitic tholeiites to be distinguished from spilitic alkali basalts. The total content of REE in spilites derived from known basaltic parents shows a small

be used to distinguish tholeiites from alkali basalts. To determine if alteration has changed the La/Yb ratio of a basaltic suite it is necessary to use a plot such as Fig. 1, before this ratio is applied to petrogenetic modelling. The designation of spilitic rocks to one magmatic series or another is important in elucidating the nature of ancient volcanism and must be determined using a variety of geochemical 'immobile' parameters. Figure 1d summarises the alteration trends and marks a boundary between altered tholeiites and alkali basalts. This division remains highly tentative, however, until alkali basalts, hydrated to the same level as some tholeiites, have been analysed to check if any change in their La/Yb ratio takes place. If not, then alkali basalts with La/Yb ratios of ~ 10 –12 will overlap with altered tholeiites containing 5–6% H_2O^+ by weight. Both the no-alteration trend (NAT) and the hydrous alteration trend (HAT) are characterised by greenschist facies spilites and very low-grade alteration (submarine weathering) of basalts. What factors determine which of these two main trends develop is unclear (longevity of burial; sedimentation rate; nature of lava units?) and in particular why do modern spilites follow NAT and ancient spilites follow HAT? The Bhoiwada trend

(BAT) is also shown, although further studies are required to substantiate this type of alteration.

I thank Dr J. A. Winchester for helpful comments.

Transuranic depositional history in South Greenland firn layers

The surface layers of the Greenland ice sheet have preserved a continuous and detailed record of atmospheric fallout of transuranic nuclides from weapons tests over the past 30 yr. The ages of the glacial strata were determined by ^{210}Pb geochronologies. We found that the influence of remobilised soil debris with their sorbed transuranics does not seem to be important, and that fallout maxima occurred in the 1950s and 1960s for $^{239+240}\text{Pu}$ and in 1965–66 for ^{238}Pu . This work may be extended by using alpine glaciers in mid-latitudes for a reconstruction of fallout patterns over the past three decades and for an evaluation of present day dispersions of these nuclides as a consequence of atmospheric fallout and other possible entries through the nuclear fuel cycle.

The observed or measured stratigraphic layers found in glaciers of the polar regions are very attractive for studies of the various species of atmospheric fallout including pollutants. Although glaciers are found at nearly every latitude of the Earth, it is the inland areas of the Greenland and Antarctica ice sheets that provide the most reliable stratigraphical relations¹. This is because summer melting is negligible or non-existent, and orderly sequential buildup is not destroyed by percolation. The snow or firn and the dissolved and particulate substances are essentially immobile following deposition². A number of geochronologies, both radiometric and stratigraphic, allow the introduction of time frames into the layered systems; in many instances, the season of the year, as well as the year itself, can be identified³. The fluxes of some metals from the atmosphere to the glaciers over the past centuries and millenia have identified both the anthropogenic and natural contributions^{4–8}. The fallout of nuclear debris from weapons testing has been observed in both the Arctic and Antarctic glaciers through gross β , ^{90}Sr and ^{137}Cs measurements^{9–13}. With increasing concerns about the dispersion of transuranics in our environment, it was of interest to develop the

pollution history of Pu and Am isotopes from a Greenland ice sheet location.

During the 1975 field operations of the Greenland Ice Sheet Program (GISP) a 30-m deep, 7.6-cm diameter firn core was augered at a location designated 'South Dome' Greenland ($63^{\circ}31.6'\text{N}$, $44^{\circ}34.5'\text{W}$). The June 1975 surface serves as the zero depth horizon. A lightweight mechanical drill was used¹⁴. Both the core and the chips formed during drilling were collected in the same polyethylene bag from each approximate 1-m run of the drill. After being transported frozen to the US, the 4–9-kg samples (dependent on the general increasing density with depth) were transferred to 10-l polyethylene containers, rapidly melted in a microwave oven and acidified to a pH of 1 with HNO_3 .

The chemical analyses were performed on the residues obtained by the evaporations of the 4–9-l of melt water. Pu analyses were carried out¹⁵. Following melting, the waters were acidified with HNO_3 . Later, spikes of Pb carrier and the tracers ^{242}Pu and ^{243}Am were added. The Am contents were determined by a modification of an unpublished method¹⁶. ^{210}Pb assays were made by a routine method developed at the Scripps Institution of Oceanography¹⁷.

The sedimentation rate over the 30-m profile averaged 1 m yr^{-1} for the gross glacial material or 0.6 m yr^{-1} of water equivalent, after density corrections on the basis of ^{210}Pb chronology (Fig. 1; ref. 18). This value compares well with the accumulation rate determined on the basis of firn stratigraphy and oxygen isotopes (Dansgaard et al., personal communication).

Table 1 $^{241}\text{Pu}/^{239+240}\text{Pu}$ ratios, computed at various depths in the Greenland Glacier for the year 1962

Depth (m) water equivalent	Time (yr)	$^{241}/^{239+240}\text{Pu}^*$
0–0.58	0–1.0	31.4
0.58–1.06	1.0–1.7	35.3
1.06–1.45	1.7–2.4	45.0
1.45–1.83	2.4–3.0	21.5
1.65–2.14	3.0–3.5	26.9
2.14–5.28	3.5–4.2	11.1
2.58–3.10	4.2–5.1	15.6
3.10–4.14	5.1–6.7	13.2
4.14–5.16	6.7–8.5	32.0
5.16–5.73	8.5–9.4	14.1
5.73–6.37	9.4–10.4	16.0
6.37–7.03	10.4–11.5	17.1
7.03–7.72	11.5–12.0	18.9
7.72–8.46	12.0–13.0	11.5
8.46–9.02	13.0–14.8	16.9
9.02–9.51	14.8–15.6	11.1

11.77–12.3	19.3–20.2	23.2
12.3–12.9	20.2–21.1	21.6
12.9–13.5	21.1–22.1	26.4
13.5–14.1	22.1–23.0	28.6
14.1–15.4	23.0–25.3	24.7
15.4–16.5	25.3–27.1	39.2
17.8–19.2	29.2–31.5	32.8

*For 0–13.9 yr ago, the $^{241}\text{Pu}/^{239+240}\text{Pu}$ are normalised to a parameter of ^{241}Pu in July 1962 at which time the level of ^{241}Am was zero. For times 13.9–22.1 yr ago, a similar normalisation was made to 1954. For earlier times, the ^{241}Pu is calculated assuming ^{241}Am was zero at this time and decay is taken into account.

The Pu and Am isotopic concentrations as a function of time of deposition or of depth are shown in Fig. 1 with the ^{210}Pb concentrations which were used to establish one of the chronologies. Two distinct maxima are observed for $^{239+240}\text{Pu}$ for the periods 1963–65 and 1955–60. A third maximum may exist in the strata deposited between 1946 and 1948, and may reflect the Nagasaki, Hiroshima and/or Almagordo, New Mexico weapon detonations. The ^{238}Pu profile in the glacial deposits is similar to that of the $^{239+240}\text{Pu}$ up to 1966. The input of this isotope from the burn-up of the SNAP-9A device in 1964, is not recorded in the

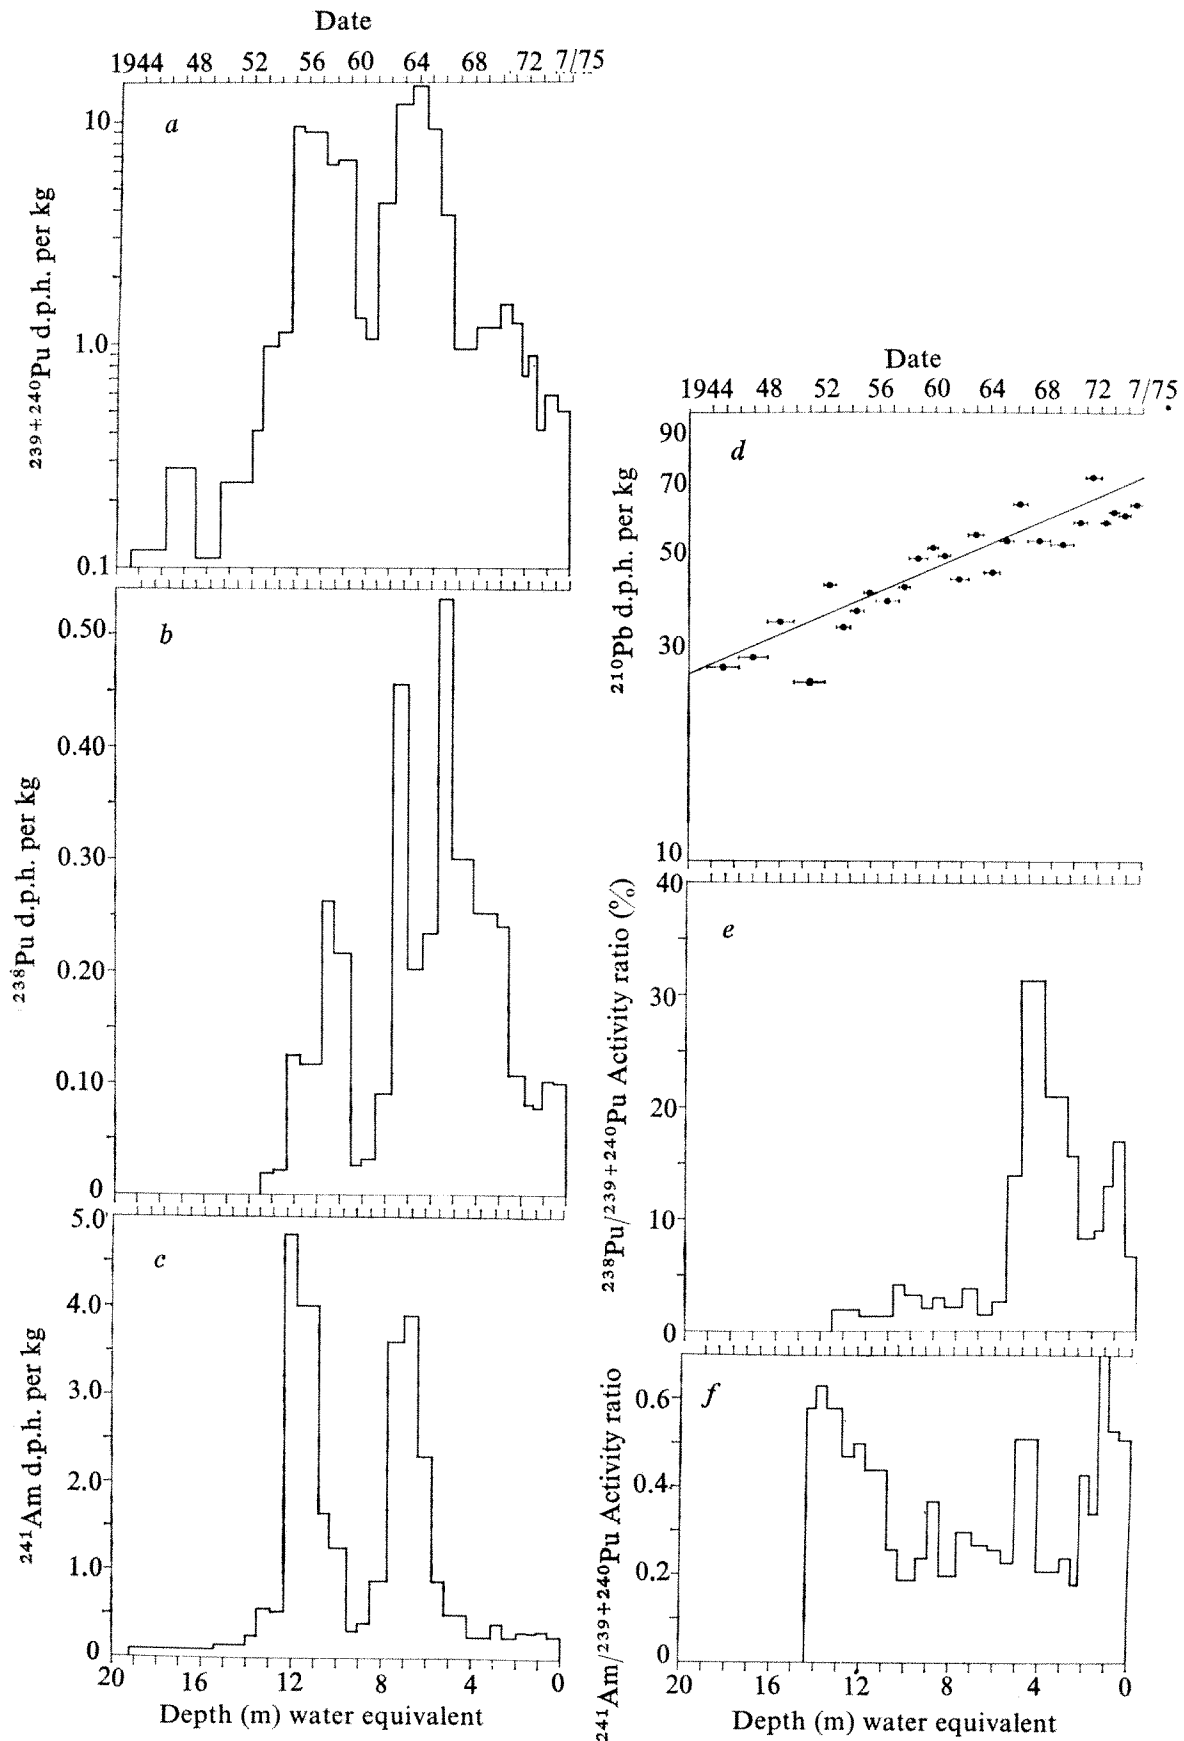

Fig. 1 *a-d*, $^{239} + ^{240}\text{Pu}$, ^{238}Pu , ^{241}Am and ^{210}Pb activities in the Greenland Ice Sheet. *e, f*, The $^{238}\text{Pu}/^{239} + ^{240}\text{Pu}$ and $^{241}\text{Am}/^{239} + ^{240}\text{Pu}$ activity ratios in the Ice Sheet. The timescale is based on the ^{210}Pb geochronology. The counting errors for these nuclides were higher for the surface samples, as a consequence of small sample size, and for the deeper samples, as a consequence of low concentrations of the nuclides. The average counting errors and their ranges (in parentheses) are: $^{239} + ^{240}\text{Pu}$, 7.4% (2.8–15.6); ^{241}Am , 13% (6.2–33); and $^{238}\text{Pu}/^{239} + ^{240}\text{Pu}$, 31% (12.5–53). For ^{210}Pb , the counting errors were 3% or less for all samples.

glacier until 1966. The patterns of ^{241}Am levels are in concord with that of $^{239+240}\text{Pu}$; this nuclide grows in from the decay of its parent ^{241}Pu , produced in weapons testing along with the other Pu isotopes.

The most extensive record of plutonium fallout from the atmosphere as a function of latitude (for samples collected between October 1970 and January 1971) has been carried out by the Health and Safety Laboratory of ERDA in New York¹⁹. Soil samples to a depth of 30 cm, with a surface area of 622 cm² were collected at 65 sites. The assumption was made that the soils were undisturbed and had integrated weapons fallout over the past 25 yr or so. There is, however, strong evidence that soils can be mobilised by winds and waters with a consequential alteration of the fallout record. Coastal sediments often show increasing $^{239+240}\text{Pu}$ fluxes from the 1950s to the present, whereas if stratospheric fallout were the only entry, maxima would be expected in the late 1950s and early 1960s.

The contribution of soil mobilised $^{239+240}\text{Pu}$ to the amount of these isotopes in the Greenland ice sheet can be estimated in the following way. Windom²⁰ has indicated that the fallout rate of particles in a Greenland glacier is 21 mg per cm² per 10³ yr. If we assume a Pu activity of 1.0 d.p.m. per g for atmospheric particles, similar to that observed for northern hemispheric dusts¹⁵, then the remobilised soil debris is contributing 2.1×10^{-5} d.p.m. per cm² per yr. For surface samples of the glacier, there is an accumulation rate of 60 cm, water equivalent per yr, or 0.06 kg per cm² per yr¹. Using a $^{239+240}\text{Pu}$ concentration of 0.01 d.p.m. per kg for the surface strata of the glacier, the total flux of $^{239+240}\text{Pu}$ is of the order of 6×10^{-4} d.p.m. per cm² per yr. Thus, the soil remobilised $^{239+240}\text{Pu}$ may contribute the order of 5% of the total burden of these isotopes in the glacier.

On the basis of the soil record, there has been a cumulative fallout of $^{239+240}\text{Pu}$ for northern latitudes between 60° and 70°N of 1.6 ± 1.0 mCi km⁻² up to 1971. Our integrated value for the ice sheet accumulation through 1975, 0.7 mCi per km², agrees with the previous value.

Through a comparison of transuranic and ^{210}Pb concentrations in a sample collected about 14°N of the one analysed in this work (Camp Century, 77°10'N, 61°08'W; elevation of 1,886 m)⁷, it seems that there may be a uniform fallout of these nuclides over a wide area in Greenland. The Camp Century collection was made in 1965 and the upper layers which were analysed represented snow deposited between the Autumn of 1964 and the Summer of 1965. The concentration of the nuclides in the Camp Century surface layers and 'South Dome' 6 m stratum, corresponding to a time about 1965, are: $^{239+240}\text{Pu}$, 11.3 ± 0.003 and 9.3 d.p.h. kg⁻¹; ^{241}Am , 2.7 ± 0.18 and 2.3 d.p.h. kg⁻¹; $^{238}\text{Pu}/^{239+240}\text{Pu}$, 0.012 ± 0.003 and 0.026 ± 0.005 . The ^{210}Pb of the Camp Century and of a site analysed by Windom²⁰, both decay corrected to the same time, are 96.4 ± 2 and 100 d.p.h. kg⁻¹. These arrangements help dispel the idea that perhaps the results are site specific for any given glacier sample.

Finally, we have examined the ^{241}Am fallout record in relation to that of $^{239+240}\text{Pu}$. It is generally assumed that the ^{241}Am in the environment today arises nearly completely from the decay of ^{241}Pu (half life 14.9 yr) produced in nuclear weapons tests. Although a large number of tests have contributed ^{241}Pu to the environment, we have obtained the ratio $^{241}\text{Pu}/^{239+240}\text{Pu}$ for July 1962 for samples deposited after this time period, for 1954–62 for samples deposited in this interval and for years before 1954. These calculations are described by Livingston *et al.*²¹. These authors indicate that a ratio of 13–14 in fresh debris for the 1961–62 US/USSR tests is representative and clearly our results following the 3.5 most recent years seem to agree with these data. The most recent values of the ratio, ranging from 21.5 to 45, are perhaps explicable by inputs from recent Chinese tests. It should be pointed out that because of small sample sizes, these ratios are less accurate for the near surface and pre-1954 samples.

This research was supported under a Contract with the Energy Research and Development Administration, Environmental Sciences Branch, Division of Biology and Medicine (ERDA E (04-3)-34 P. A. 84) and the National Science Foundation, Division of

Polar Programs (OPP 7609120). Ms Sue Johnson assisted with the transuranic analyses.

Angiosperm fossils from latitude 70°S

WE have found fossil angiosperm leaves more than 1,000 km further south than any other previously reported. Specimens were obtained *in situ* by R. W. B. from tuffs in a volcanic sequence in the eastern Elgar Uplands of northern Alexander Island (Fig. 1). Hitherto in Antarctica, angiosperm macrofossils have been reported only from the northern Antarctic Peninsula area in Tertiary sediments on Seymour Island¹ and in volcanoclastic sequences on King George Island, South Shetland Islands^{2,3}, although angiosperm microfossils, mainly pollen, have been found in erratics of marine sandstone from the McMurdo Sound area⁴. The source area of these latter specimens however, is not known, and it is well known that some pollens, including that of *Nothofagus*, can be transported in detectable quantities over large distances⁵. No macro plant fossils seem to be associated with the McMurdo Sound pollen.

The flora from the Elgar Uplands is poorly preserved but includes the impressions of at least two kinds of leaf (Fig. 2). Numerous carbonised films and moulds, representing accumulation of logs and branches, also occur in north-western Elgar Uplands. The most common kind of leaf (Fig. 2a–c) reaches in excess of 10 cm long and the venation suggest that it had a broad-based ovate outline, although the margin is not clearly delineated on any of the specimens. There is a straight slender mid-vein from which secondary veins branch at angles of 30–40°. On one possible variant (Fig. 2d) this angle of secondary origin is 50° or more. Small fragments of the leaves indicate that each vein terminates in a serration at the leaf margin (Fig. 2a and b). Similar leaf characteristics are commonly observed on specimens from the South Shetland Islands, some of which have been illustrated as *Nothofagus* or '*Fagus*'⁶. Although the present examples are considerably larger than modern species of *Nothofagus* occurring in Patagonia, they are comparable in size with others from New Guinea, New South Wales and the Queensland rain forest. A second kind of leaf (Fig. 2f) is much broader than the first, has an entire margin and an obtusely pointed apex. The mid-vein is slightly sinuous and gives off thin and curved secondary veins at irregular

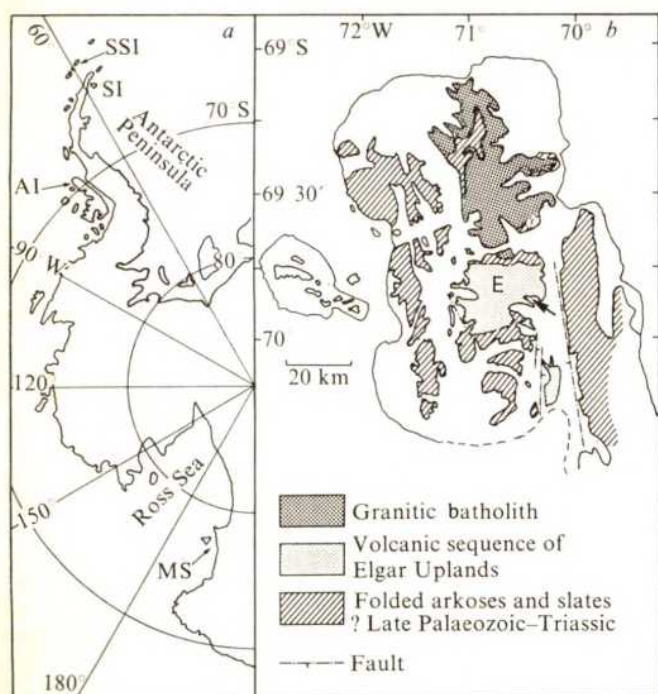

Fig. 1 Maps of Antarctic fossil angiosperm localities. *a*, Lesser Antarctica: AI, Alexander Island; MS, McMurdo Sound; SI, Seymour Island; SSI South Shetland Islands. *b*, Geological map of northern Alexander Island, showing the newly discovered fossil leaf locality (arrow). E, Elgar Uplands.

intervals. The secondary veins seem to have stout triangular bases where they join the mid-vein, but it is possible that this is an accident of preservation rather than an original feature. A fragment of leaf base (Fig. 2e) shows irregular venation which suggests closer affinities to the second kind of leaf than the first.

The plant-bearing tuffs occur in a sequence of tuffs, lavas and agglomerates, more than 500 m thick⁷ which crops out over most of Elgar Uplands. The lavas are dominantly basaltic with phenocrysts of zoned labradorite, augite and hypersthene. Only one andesite has been recorded but alteration may preclude their petrological determination. Hornblende together with labradorite are common constituents in the tuffs. All the rocks are extensively altered with abundant calcite, epidote, chlorite and pyrite, and there is widespread silification. A much later stage of volcanism in the area is probably represented by isolated outcrops of fresh vesicular breccias, palagonite breccia and a vesicular olivine basalt plug. These are closely comparable with late Cainozoic volcanic rocks described from Beethoven Peninsula, Alexander Island⁸.

Beneath the volcanic sequences there is a thick succession of deformed sedimentary rocks, assigned to the late Palaeozoic on the basis of fossil spores⁹ and general similarities to comparable rocks elsewhere in the Antarctic Peninsula¹⁰. A late Triassic marine fauna however, has recently been obtained from the (?) upper part of this sequence¹¹.

Field relationships thus set only broad age limits on the plant-bearing tuffs and their precise age is difficult to assess. A K/Ar date of 70 Myr was obtained from a tuff in the lower part of a supposedly related sequence in the nearby Colbert Mountains¹² and this suggests a post-Cretaceous age for much of the volcanic successions. The leaves are too poorly preserved to be identified with certainty but they show some resemblance to those in the South Shetland Islands. Few published accounts of these are available, although one flora from King George Island was assigned to the Miocene on palaeobotanical evidence³. Associated lavas

have now been dated at about 60 Myr (R. J. Pankhurst, personal communication).

These fossils indicate that at some stage in the Tertiary, Alexander Island was colonised by arborescent angiosperms, and their proven *in situ* occurrence is extended 1,000 km south of the northern Antarctic Peninsula area. It is unlikely that Antarctica has moved much since 40 Myr ago¹³ and therefore they point further to a considerably warmer climate than now at approximately the same latitude. The large size of some leaves (>10 cm) could be interpreted to favour the existence of a warm-temperate to subtropical climate¹⁴, but it is unlikely that the present flora is indicative of more than ordinary to warm-temperate conditions.

Evidence has been cited for early and late Cainozoic glaciation in Antarctica, but a review of the data¹⁵ suggests that full-bodied ice sheets developed first in Greater Antarctica sometime after the Lower Miocene (25 Myr ago) and at a later date in Lesser Antarctica. This is supported by fossil evidence from the Ross Sea¹⁶ where microfloral remains in Oligocene glacial deposits are interpreted as representing cool-temperate vegetation, which was finally eliminated in the Miocene.

Although the fossil angiosperm leaves described in this paper are undoubtedly the southernmost yet known, the occurrence of degraded plant tissue, cuticle and vascular fragments, in the Oligocene deposits in the Ross Sea, is thought to indicate a nearby vegetation source in that area¹⁶. Knowledge of the area suggests that, if the source rocks are still preserved, they are hidden by ice.

Fig. 2 Camera lucida sketches of fossil angiosperm leaves from Elgar Uplands, Alexander Island.

The fossils are housed in the collections of the British Antarctic Survey at Cambridge. We thank Dr Leo J. Hickey for helpful discussion. The radiometric age date from the South Shetland Islands was determined by Dr R. J. Pankhurst from specimens collected by Dr S. D. Weaver.

Megafaunal biomass in the deep sea

THE conventional notion of the deep-sea ecosystem has been one where a rain of fine organic particles from above provides food for a great diversity of small creatures living in and on the sediments^{1–3}. These, the meiofauna and macrofauna, live as deposit feeders, suspension feeders, and, in lesser proportion, as carnivores preying on other members of the fauna. The macrofauna in turn are thought to provide food for the generally more carnivorous megafauna, the echinoderms, decapods, and fishes. Although no data have been published concerning the abundance of the deep-sea megafauna in terms of biomass, the assumed trophic relationship and the Eltonian concept has led to the common feeling that the biomass of this component must be small in comparison to the meiofaunal and macrofaunal biomass⁴. Our data show that, on the contrary, the megafaunal biomass approaches that measured in the macrofauna. This observation re-focuses attention on the question of food supply to the deep sea, and implies that previously

suggested falls of large dead animals from the pelagial^{5,6} may be important.

As part of a general study of the distribution and ecology of deep benthic communities, we have made 116 trawl collections on the continental slope, rise, and abyss in the western Atlantic south of New England. Our principal gear for deep bottom trawling has been a 41-ft Gulf of Mexico shrimp trawl of 2.5-cm stretch mesh and fished with steel V doors. We have used a smaller 16-ft semiballoon trawl at slope depths. The animals obtained have been identified to species, counted, and weighed wet, usually after preservation in 10% formalin. From these data, we have determined mean wet weight per specimen for every taxon as a function of depth. Absolute abundance estimates were derived from photographic series made with a pair of E.G. & G. cameras mounted on DSRV ALVIN and fired at a rate of one frame per 10 s as the submersible cruised along a measured transect. Over 3,500 frames have been analysed from eight dives (436, 583, 586, 587, 589, 590, 591 and 592) in the same area where the trawling was carried out. Absolute abundance times mean weight within the appropriate depth interval gives the biomass. The data for deep benthic fishes, which comprise as a group about 40% of the total wet weight of megafaunal biomass in our trawl collections, are shown in Table 1.

The only previously available data concerning macrofaunal biomass off southern New England does not differ significantly ($P>0.65$) from the megafaunal (fish) data of Table 1. Most of these data, however, were taken with anchor dredges and seem to underestimate biomass considerably. New data on macrofaunal biomass off southern New England, obtained from 57 DSRV-operated box-core samples sieved through a 0.42-mm screen, were therefore used, and are plotted in Fig. 1. Total megafaunal biomass is obtained by extrapolation from the data of Table 1, using the actual weight percentage comprised by fish in each of the 46 trawls as the conversion factor.

Figure 1 compares macrofaunal and megafaunal biomass in the deep water south of New England. They are essentially of the same order of magnitude. The assumption that the biomass of the larger animals is relatively insignificant⁴ seems to be unfounded. Unless turnover rates in the macrofauna are relatively very high—and all the evidence suggests that this is not the case^{8,9}—the megafaunal biomass cannot be supported by the macrofauna. The megafauna must therefore depend to a considerable extent on food arriving from pelagic regions in the form of large, fast-falling packets, that is, the bodies of fishes, whales, squids and decapods. Based on observations made with a baited deep-sea camera, it has been suggested that this source could form an important fraction of the nutrition for the deep-sea

Table 1 Abundance and biomass of demersal fishes on the continental slope and rise

Columns 1–3 contain data from the submersible; columns 4–7 are from trawls at the same approximate depths. Abundance data marked with an asterisk are from Grassle *et al.*¹⁶

Fig. 1 Biomass against depth in macrofaunal infauna (○) and megafauna (×). The regression line is for the infaunal data ($\log_{10}B \text{ (g m}^{-2}\text{)} = 1.44 - 0.41Z(\text{km})$; $r = -0.58$, $P < 0.001$).

benthic ecosystem⁵. Our data support this idea. Further support is found in studies of the food habits of *Coryphaenoides armatus*, the dominant macrourid fish on the continental rise. This species accounts for as much as 80% of the fish biomass there and depends on large pelagic creatures for its food^{10,11}.

The need to search wide barren areas for a few randomly occurring food items and the fact that the metabolic demands of a large animal are less per unit weight than for a small one¹² should select for large efficient seekers in the deep-sea megafauna. Figure 2 shows the relationship between mean individual fish weight and depth, based on the trawled material of Table 1. There is a dramatic increase at the beginning of the rise near 2,000 m. The 'bigger-deeper' phenomenon, shown here for all fish taxa combined, applies as well within individual species and seems to be quite common in deeper-living marine fishes¹³. (Our data indicate that only a few megafaunal invertebrates are 'bigger-deeper', and the red crab *Geryon* is 'smaller-deeper' (ref. 14.) The efficiency of large deep-benthic fishes is evidenced by the rapidity with which they assemble to baited cameras⁵.

Based primarily on studies of the meiofaunal and macrofaunal elements of the deep-sea benthos, it has been suggested that small forms should dominate food-limited associations¹⁵. Our consideration of the megafaunal fishes implies just the opposite. The point is that both life styles are possible in the deep sea, particularly in the case where

the faunal components are relatively independent of one another. Where mobility is important, large size will be selected for, but where the ability to live in a fine-grained sediment and to feed on a thin organic layer is important, small size will be the rule.

We thank R. Carney, J. F. Grassle, R. R. Hessler, H. L. Sanders, and R. D. Turner for their comments on the manuscript. C. H. Clifford and P. T. Polloni assisted in the photo analyses and at sea. D. M. Cohen was the principal observer on all ALVIN dives, and has provided help and encouragement of this work in all its stages. Support came from the NSF and the National Oceanic and Atmospheric Agency.

Ultradian rhythms in urine flow in waking humans

THERE is evidence that neural oscillators may regulate the flow of urine, Mandell *et al.*¹ demonstrated ultradian rhythms in urine flow in catheterised patients during sleep, synchronised with the sleep REM-nonREM cycles (REM, rapid eye movement). They attributed these rhythms to rhythmic secretion of antidiuretic hormone (ADH) during sleep. Others have demonstrated episodic secretion of ADH during sleep but no correlation with REM-nonREM cycles². Reports³⁻¹⁰ of ultradian rhythms of 90-100 min analogous to the REM-nonREM cycles in waking subjects in physiological, endocrine and psychological processes, suggested the existence of waking ultradian rhythms in the flow of urine. We report here two experiments which demonstrate these rhythms.

In experiment 1 eight healthy, male college students aged 18-20 yr, paid to participate, and unaware of the hypothesis, avoided alcohol and drugs for 24 h preceding the study. To avoid catheterisation, subjects were required to drink a constant amount of fluid and then to urinate as much as possible every 10 min for the next 10 h. Each began between 10:00 h and 13:00 h. Two subjects drank 30 ml of commercial calorie balanced liquid food, two drank 50 ml of liquid food, and four drank 30 ml of liquid food plus 30 ml of water. Each sample was collected into a graduated cylinder and volume was measured to the nearest ml. After each voiding subjects were given a brief perceptual task lasting approximately 40 s (ref. 10). When not voiding subjects were required to remain seated but could read, write, listen to music or talk to each other (all were tested in pairs).

In the second experiment, 12 healthy, male college students, aged 19-25 yr were tested in a similar way. Subjects drank 25 ml of fruit juice plus 25 ml of water. Part of each 10-min urine sample was frozen immediately for analysis. As before, after each voiding, subjects were

Fig. 2 Mean weight of fish against depth. Data from Table 1. The regression is significant ($W(g) = 0.18Z(m) - 57.3$; $r = 0.73$, $P < 0.002$).

given a brief perceptual task and then remained seated until the next trial.

In spite of the heavy experimental demands 17 out of the 20 subjects provided urine at all 60 attempts. Data for three subjects, two from the first experiment and one from the second, had to be discarded because they had failed to urinate on 10 consecutive attempts. Prominent ultradian rhythms were visible in the flow of urine for most subjects during the 10 h. Figure 1 shows the record of a representative subject in the second experiment. The mean coefficients of variation (s.d./x) for urine volumes were 34.5% and 42% for the first and second study respectively; the overall range varied between 72% and 24%. Na^+ and K^+ concentrations measured by flame photometry for 11 subjects of the second experiment, and urinary osmolality measured with a freezing point osmometer for seven subjects, showed identical rhythms reciprocal in-phase to the rhythms in urine flow.

The statistical significance of the ultradian rhythmicity was determined by time series analysis and inferential statistical procedures. First, the mean for each time series of urine volumes, K^+ and Na^+ concentrations and urine osmolality were subtracted from each data point, and the linear trend was eliminated. Then, autocorrelation functions were computed and the variance spectra were estimated^{11,12}. Spectra were calculated for 10 orthogonal frequencies from 0 to 64.8 cycles per day, in increments of 7.2 cycles per day. For each variable, spectra were hanned (hanning is a smoothing procedure to increase the reliability of the spectral estimates) individually, normalised and then averaged across all subjects. Cross correlation functions, hanned, normalised cross spectra and cross spectral phase angles were also computed for the same 10 spectral frequencies between all pairs of variables for each subject. Average spectra peaked at 14.4 cycles per day (corresponding to 1 cycle every 80–133 min) for all variables (Fig. 2). We had predicted that variance would peak in the spectra at 14.4 cycles per day, so we compared the variance at this frequency with variance at the adjacent spectral frequencies and with the mean variance at the rest of the spectral frequencies, by one-tailed *t* tests. All six comparisons yielded significant *t* ratios in the expected direction ($P < 0.05$, or better).

The ultradian rhythms in urine flow were clearly out of phase with electrolyte concentrations and osmolality rhythms. Pearson product moment correlations between volume time series and electrolyte concentrations and osmolality were negative for all subjects, and differed significantly from zero ($P < 0.001$) for all three variables. Similarly, cross-spectral phase analysis revealed that K^+ , Na^+ and osmolality were in-phase with each other and about 180° out-of-phase with urine volume.

Our results demonstrate prominent ultradian rhythms in urine flow of waking subjects. Although we do not

Fig. 1 Time series constructed from raw data of urine volumes sampled every 10 min from 1200 until 2200. Spectral analysis revealed a dominant ultradian periodicity of approximately 80–133 min per cycle.

Fig. 2 Average spectra for urine volumes (\square , $n = 17$), osmolality (\circ , $n = 7$), K^+ (\bullet , $n = 11$) and Na^+ (\triangle , $n = 11$) concentrations. All spectra peaked at 14.4 cycles per day (corresponding to 80–133 min per cycle).

know whether these were generated by the oscillatory processes underlying the REM–nonREM cycles and the sleep urinary rhythms, the reciprocal phase relationships between volumes and osmolality indicates that rhythmic secretion of ADH is responsible for the rhythms in urine flow. The reports that all anterior pituitary hormones are secreted episodically during sleep and wakefulness support such an explanation¹³. But to test this endocrinological explanation we are repeating this study, making ADH measurements concomitant with urine sampling.

The accumulation of evidence of ultradian rhythms in multiple organismic processes during both sleep and wakefulness suggest that ultradian rhythms reflect an endogenous 'biological hour' of as yet unknown function and origin, similar to the well documented 20–28-h circadian 'biological day'.

Natural selection at the α -GDH locus in *Drosophila*

THE molecular basis for the maintenance of a gene-enzyme polymorphism in natural populations of *Drosophila melanogaster* has been reported¹. The locus under analysis codes for the subunit of α -glycerophosphate dehydrogenase, (α -GDH; E.C. 1.1.1.8) a homodimeric enzyme: the primary function of this enzyme in adult muscle is to provide metabolic energy during flight²⁻⁷, and these alleles showed both spatial and temporal variations in frequency. A latitudinal cline was identified, in which the frequency of the α -GDH^S allele decreases southwards along the eastern US coast⁸. The α -GDH^S allele was also found to increase in frequency during cooler months in several New England populations⁶. We evaluated several biochemical parameters using partially purified enzyme from the three common genotypes and uncovered temperature-dependent differences in K_m , specific activity, and reaction rate constancy¹. Based on the population and biochemical data an argument was provided that environmental temperature was operating as a selective agent in demanding the relative frequencies of the two alleles at this metabolically important locus. We present here additional evidence to support this proposal, based on an evolutionary pattern of coincidence.

Fig. 1 Thermal stability of α -GDH. Partially purified enzyme (see ref. 1 for procedure) was isolated from 1-week-old *Drosophila* adults raised at 25 °C. Enzyme solutions at 39 °C were chilled, and assayed in a Guilford recording spectrophotometer, at 340 nm, for the reduction of NADH. \circ , *D. melanogaster* α -GDH^S; \blacktriangle , *D. melanogaster* α -GDH^F; \square , *D. virilis*; \times , *D. americana*; $+$, *D. arizonensis*; \bullet , *D. willistoni*; \triangle , *D. equinoxialis*.

The distinctive temporal and spatial patterns of allele frequency distribution, and the biochemical profiles discussed above, led us to refer to α -GDH^S as the cool-climate adapted allele, and α -GDH^F as the warm-climate adapted allele. This is somewhat misleading since α -GDH^F is always the most abundant allele, but as a relative statement the nomenclature is useful. We predicted that if α -GDH function is sensitive to environmental temperature a parallel response should be observed in temperature-dependent kinetic properties if we compared α -GDH of species inhabiting primarily temperate rather than tropical habitats. The observation of such parallel biochemical differentiation, in an evolutionary time frame, should carry considerable weight for the selection model in spite of our inability to experimentally demonstrate the exact *in vivo* significance of differences found in cuvette assays. Since every other *Drosophila* species reported on the essentially monomorphic at the α -GDH locus⁹⁻¹² our analysis would not be confounded by interspecific variation in our additional species samples.

Fig. 2 Apparent K_m values for the substrate, dihydroxyacetone phosphate (DHAP), for *D. melanogaster*, as a function of temperature. The strains S mark and (O) carrying α -GDH^S, and Swedish-C (Δ) carrying α -GDH^F were employed. K_m at each temperature was determined from duplicate measurements of activity at each of 5 substrate concentrations by fitting $1/v$, $1/s$ data into a linear regression computer program. Concentrations of NADH were 120 μ M throughout. Assay temperatures were maintained in the cuvette chamber by a Haake circulating water bath. Bars around representative points indicate standard error values.

We examined three tropical species (*D. willistoni*, *D. arizonensis*, *D. equinoxialis*) and two temperate species (*D. virilis* and *D. americana*) (stocks provided by the Stock Centre, University of Texas, Austin: see ref. 13). Partially purified enzyme was prepared¹ from adult homogenates of each species as well as from strains of *D. melanogaster* homozygous for the two common alleles, and studied in several ways. We found that the electrophoretic mobility of α -GDH from each of the five additional species was indistinguishable from the α -GDH^S allele of *D. melanogaster* in starch gels, in a variety of electrophoretic conditions (pH 6.8 or 8.8, in 9% or 14% starch, in a Tris-citrate buffer system; pH 7.8 or 9.8, in 9% or 14% starch, in a Tris-borate buffer system)¹⁴. This pattern of conservation, with respect to electrophoretic mobility, for α -GDH has been noted before¹⁵. But, we could detect rather large differences among the species¹ enzymes by using thermal denaturation as a probe (Fig. 1). This observation supports a growing number of studies indicating that thermal stability analysis can detect hidden variation within a single electrophoretic mobility class¹⁶⁻¹⁹. We suspect that although

Fig. 3 Apparent K_m for DHAP for α -GDH obtained from: \square , *D. willistoni*; \triangle , *D. equinoxialis*; \circ , *D. arizonensis*; \blacksquare , *D. virilis* and \bullet , *D. americana*. Assay conditions as described in Fig. 2 legend.

closely related species (for example *D. virilis* and *D. americana*, or *D. willistoni* and *D. equinoxialis*) have similar thermostability properties it is unlikely that their primary structures are the same. It is interesting to note that, as a general rule, enzyme from the tropical *Drosophila* species is less heat sensitive than enzyme from the temperate species.

Kinetic studies (Fig. 2) confirmed the distinct K_m against temperature patterns found for the *D. melanogaster* 'fast' and 'slow' homozygotes¹. The α -GDH^F pattern showed temperature independence of affinity for substrate, while the α -GDH^S pattern displayed a temperature dependent pattern in which increased substrate affinity and temperature were inversely related. This latter type of pattern has been referred to as positive thermal modulation¹⁹, a mechanism by which, it is thought, reaction rate constancy is maintained over a range of environmental temperatures¹⁹. Figure 3 summarises the data obtained for the five new species. *D. virilis* and *D. americana*, both temperate species, showed K_m against temperature profiles remarkably like the α -GDH^F pattern. In contrast, the three tropical species had profiles which, while similar within the group, clearly differed from the temperate species¹ (α -GDH^S like) pattern. In contrast to α -GDH^F, in which K_m remained essentially constant, the tropical species had a pattern of negative thermal modulation (K_m decreases with increasing temperature) over most of the temperate range. In any event the tropical species' profile clearly more resembled the α -GDH^F pattern, especially at higher assay temperatures. Activation energies were calculated from the data, and all species and genotypes had quite similar values (7.7 ± 0.8). (Energies of activation determined by Arrhenius plots according to the formula in ref. 20).

The coincidence of K_m against temperature profiles described in the data, as predicted, seem based on species distribution rather than phylogeny. This observation strongly suggests that natural selection is operating at the α -GDH locus within the genus *Drosophila*, with temperature being the mediating agent. Note that this same conclusion has been drawn for α -GDH polymorphisms in two other insect species, *Colias*, a butterfly²¹, and *Cochliomyia*, the screw worm²². We feel that a general pattern may emerge among all flying insects with a carbohydrate based energy metabolism, in which environmental temperature will be shown critical in the adaptation and evolution of flight enzyme kinetics.

Genetic control of cell division in yeast cultured at different growth rates

HARTWELL *et al.*^{1,2} have isolated a number of temperature-sensitive mutants blocked at various stages of the cell division cycle of *Saccharomyces cerevisiae*. A characteristic feature of any temperature-sensitive cell cycle mutant is its execution point in the cell cycle, that is, the point in the cycle after which cells when shifted to the restrictive temperature undergo one further cell division. If cells are shifted to the restrictive temperature before the execution point, they are unable at the elevated temperature to complete any cell division. The execution point for a particular mutant is taken to be the stage in the cycle that the defective gene completes its function. The execution point of mutant strain *cdc28* is at an earlier stage in the cycle than other cell cycle mutants³. Detailed investigations of a number of cell cycle mutants have suggested that the events in early G₁ that culminate in the execution of the *cdc28*-mediated step represent 'start'. There is evidence that passing 'start' in the cycle represents a point of commitment to division. Before the execution of the *cdc28*-mediated step, 'start', yeast is capable of several developmental programmes but after this step it is committed to the mitotic cell cycle². We report here that at generation times varying from 2.1-6.18 h 'start' occurs approximately 2 h before division. At slower growth rates the length of time from 'start' to division increases somewhat. These results are similar to the finding in the bacterium *Escherichia coli* that the time from the initiation of DNA synthesis to cell division is independent of growth rate except at slow growth rates⁴.

A number of authors⁵⁻⁷ have shown that if one knows the percentage of cells in an asynchronous culture that are past a particular event in the cell cycle, the stage in the cycle that the event occurs can be determined. The execution point of a temperature-sensitive cell cycle mutant can be calculated from the percentage increase in cell number after such a mutant is shifted from the permissive to the restrictive temperature, since this reflects the percentage of cells that are past the execution point at the time of the shift. An allowance has to be made for the fact that the age distribution of cells throughout the cycle is skewed⁸, using an equation which describes the age distribution⁷.

A strain that carries the mutation *cdc28* has been cultured at different growth rates at 24 °C in batch cultures by altering media composition and in chemostat cultures by altering the flow rate of the limiting nutrient, glucose. Cultures at different growth rates were shifted to 38 °C and cell numbers after the shift were monitored. Fig. 1 shows the effect of shifting *cdc28* with a generation time of 6.18 h to 38 °C. Cell numbers continue to increase for a time until cell division stops and a plateau in cell numbers is reached. The percentage increase in cell numbers after the temperature shift is equivalent to the percentage of cells past the *cdc28* execution point and from this data the stage in the cycle of the execution point is determined using the equation of Howell and Nabiloff⁷. In the experiment described in Fig. 1 the execution point for the *cdc28* gene product occurs at 0.42 of the cell cycle.

Table 1 shows the percentage increase in cell numbers after *cdc28* cultured at different growth rates is shifted to 38 °C. The cell number increase is greatest at the fastest growth rates and the percentage increase is least at the slowest growth rates. Clearly, if in an exponential culture many cells at the permissive temperature are past the *cdc28* execution point, this event occurs at an early stage of the cycle. Conversely, if only a few cells

Table 1 Effect of specific growth rate on the stage and time in the cell cycle of the *cdc28* gene product execution point

Specific growth rate (h^{-1})	Generation time (h)	Percentage increase in cell numbers after shift to 38 °C	Stage in the cell cycle of the <i>cdc28</i> execution point	Time before cell division of the <i>cdc28</i> execution point (h)
0.330	2.1	133	-0.12	2.5
0.254	2.73	85.7	0.11	2.4
0.180	3.85	57	0.35	2.5
0.112	6.18	50	0.42	3.58
0.032	21.6	21.4	0.72	6.05

Haploid *Saccharomyces cerevisiae* cells of strain H.185.3.5 carrying the *cdc28* mutation were grown at different steady state specific growth rates in a glucose limited chemostat at 24 °C in the media described in Fig. 1. Samples at different specific growth rates were removed from the chemostat, and diluted in fresh medium at 38 °C. Cell number was monitored at intervals as described in Fig. 1, until cell division at the restrictive temperature ceased. The percentage of cells that divided at the restrictive temperature was used to calculate the stage and time in the cycle of the *cdc28* gene product execution point using the equation described in Fig. 1.

are past this event at the time of the shift then it occurs at a late stage of the cycle. Table 1 shows that stage in the cycle of *cdc28* execution point is dependent on growth rate such that as the growth rate is slowed the execution point occurs later and later in the cycle. The time from the *cdc28* execution point to cell division is constant in cells growing with generation times of 2.1, 2.73 and

execution point for *cdc28* occurs in the previous cycle to the division which it controls, is in keeping with the view that the *cdc28* gene product decays slowly at the restrictive temperature. Others have suggested that the *cdc28* mutation is 'leaky'.

Haploid yeast cells of 'a' mating type produce a small polypeptide ' α factor' of molecular weight 1,400, which

Table 2 Effect of specific growth rate on the stage and time in the cell cycle of the α factor-sensitive step

Specific growth rate (h^{-1})	Generation time (h)	Percentage increase in cell numbers in the presence of α factor	Stage in the cell cycle of the α factor factor-sensitive step	Time before cell division of the α factor-sensitive step
0.256	2.7	56.9	0.13	2.35
0.20	3.46	60	0.33	2.32
0.15	4.62	42.8	0.49	2.36
0.112	6.18	28.5	0.63	2.29
0.076	9.1	26.6	0.65	3.18

Haploid *Saccharomyces cerevisiae* cells of strain H185.3.4 carrying the *cdc28* mutation were grown at different steady-state specific growth rates in a glucose limited chemostat at 24 °C in the media described in Fig. 1. Samples at different specific growth rates were removed from the chemostat, and diluted in fresh medium at 24 °C containing α factor. The α factor was purified as described previously⁸, and a concentration of α factor was chosen that produced greater than 95% unbudded cells and that inhibited budding for at least 8 h. Cell number was monitored at intervals as described in Fig. 1, until cell division in the presence of α factor ceased. The percentage of cells that divided in the presence of α factor was used to calculate the stage and time in the cycle of the α factor sensitive step using the equation described in Fig. 1.

3.85 h but at slower growth rates it expands in time. A possible explanation for this expansion is that the *cdc28*-thermosensitive gene product decays quite slowly at 38 °C. If this is true then the gene product will continue to function for some time at the restrictive temperature, and consequently these cells will continue to divide. The result of this is that the execution point for *cdc28* will seem to be earlier in the cycle than the time at which the gene product normally completes its function. Our observation (Table 1) that at fast growth rates the

contains a number of common amino acids⁸. When the α factor is added to cells of 'a' mating type, the latter are arrested as small unbudded cells before the initiation of DNA synthesis. The point of α factor-mediated cell cycle arrest has been mapped within the sequence of three gene functions before the initiation of DNA synthesis, and it has been shown that the α factor-sensitive step is the same as that mediated by the *cdc28* gene product³.

Because of the uncertainty attached to precise location

Table 3 Effect of growing *Saccharomyces cerevisiae* in different media supporting different growth rates on the stage and time in the cell cycle of the α factor-sensitive step

Culture medium	Specific growth rate (h^{-1})	Generation time (h)	Percentage increase in cell numbers in the presence of α factor	Stage in the cell cycle of the α factor-sensitive step	Time before cell division of the α factor-sensitive step
YEPA	0.247	2.8	57.0	0.35	1.83
Proline	0.208	3.33	50.0	0.42	1.93
YEPG	0.134	5.16	30.5	0.62	1.96
Ethanol	0.084	8.3	22.0	0.71	2.41
Acetate	0.082	8.5	21.5	0.72	2.38

Haploid wild-type *Saccharomyces cerevisiae* strain A364a were grown on different media at 24 °C. The media were: YEPA, containing in 1 l of distilled water, 10 g yeast extract, 20 g bacto-peptone, 20 g glucose; proline, containing in 1 l of distilled water, 2 g proline, 20 g glucose, 1.4 g yeast nitrogen base without amino acids; YEPG, containing in 1 l of distilled water, 10 g yeast extract, 20 g bacto-peptone, 20 ml glycerol; ethanol, containing in 1 l of distilled water, 20 ml ethyl alcohol 95%, 5 g ammonium sulphate, 6.7 g yeast nitrogen base without amino acids; and acetate, containing in 1 l of distilled water, 20 g potassium acetate, 6.7 g yeast nitrogen base without amino acids. All these media, except YEPG and YEPA, also contained 0.04 g tyrosine, 0.04 g lysine, 0.04 g histidine, 0.01 g uracil and 0.1 g adenine per l, trace elements and vitamins. Cultures were grown on rotary shakers at 24 °C. These media support generation times of 2.8, 3.33, 5.16, 8.3 and 8.5 h respectively. Samples at different growth rates were diluted in fresh YEPA medium at 24 °C containing α factor. Cell number was monitored at intervals as described in Fig. 1, until cell division ceased in the presence of α factor. The percentage of cells that divided in the presence of α factor was used to calculate the stage and time in the cell division cycle of the α factor-sensitive step using the equation described in Fig. 1.

in time of the *cdc28* execution point, we have determined the stage and time in the cycle of the α factor-sensitive step for cells cultured at different growth rates in the chemostat and treated with α factor; the percentage of cells that divide in the presence of α factor was used as before to determine the stage in the cycle of the α factor-sensitive step. Table 2 shows that for cells cultured at different growth rates in the chemostat the α factor step was at the beginning of the cycle at fast growth rates, but as the growth rate was slowed it moved to later stages of the cycle. In terms of time, however, it occurred at generation times less than 6.18 h, a constant time before cell division. Similar results were obtained when the time of the α factor-sensitive step was investigated in cells grown at different growth rates using different media in batch culture (Table 3). At longer generation times the time from 'start' to cell division increases; for instance, at a generation time of 9.1 h the time from

Fig. 1 Effect on cell division of shifting *cdc28* previously grown with a doubling time of 6.18 h at 24 °C in a chemostat to the restrictive temperature 38 °C. Haploid *Saccharomyces cerevisiae* cells of strain H185.3.4 carrying the *cdc28-1* mutation were grown at 24 °C in a chemostat (L.H. Engineering) at a steady-state specific growth rate of 0.112 h⁻¹ (generation time 6.18 h). The chemostat medium contained 10 g yeast extract, 10 g bacto-peptone, 10 g glucose as limiting nutrient, 5 g ammonium sulphate, 2 g ammonium phosphate, 1 g magnesium sulphate and 100 mg adenine in 1 litre of distilled water at pH 5.5. Samples were removed from the chemostat diluted in fresh medium and one sample was incubated at 24 °C (●) and the other at 38 °C (□) in a shaking water bath. Samples were removed from both cultures at intervals, diluted in Isoton (Coulter Electronics) and cell numbers determined in an electronic particle counter (Coulter Electronics) after 90 s treatment with an MSE homogeniser to break up clumps. The percentage increase in cell numbers after the shift to 38 °C (in this case 50%) was used to determine the stage in the cycle of the *cdc28* execution point using the equation

$$X = 1 - \frac{\ln(N/N_0)}{0.693}$$

where X is the stage in the cycle of the execution point, N_0 is equal to the cell number at the time of the temperature shift and N is equal to the final cell number at the restrictive temperature⁶. The stage in the cell cycle of the execution point was calculated to be 0.42.

'start' to cell division was 3.18 h (Table 2). The results presented in Table 1 can also be interpreted to indicate that at very slow growth rates the time from 'start' to cell division lengthens. If the decay time for the *cdc28* gene product is the same at varying growth rates, a constant amount should be subtracted from the time between the apparent execution point and cell division in the last column of Table 1. This would leave this time constant for generation times between 2.1 h and 3.85 h; and if, for example, the decay time took 0.2 h the time from the real execution point to cell division would be nearly the same as the equivalent 'start-division' time in the last column of Table 2. This assumption of a constant decay time, however, would not explain the increased 'start-division' time of for instance 6.05 h found for cells grown with a generation time of 21.6 h (Table 1).

These results indicate that for cells growing with generation times of less than 6.18 h the cell cycle can be divided into an expandable phase before the α factor-sensitive step, the length of which is dependent on growth rate, and a constant phase from the α factor-sensitive step to cell division, the length of which is independent of growth rate. As the α factor step is the same as that mediated by the *cdc28* gene product, which is thought to represent 'start', our results indicate that once cells pass 'start' they proceed to cell division in a constant time regardless of growth rate. Cells take a variable time to reach 'start' at different growth rates. It is interesting to note that when yeast populations were grown at long generation times in a chemostat the budded phase of the cycle was slightly longer than during rapid growth while the unbudded phase was selectively lengthened¹⁰.

At longer generation times the 'start-division' time increased although the pre-start period of the cycle was the main expandable phase. Our results are reminiscent of observations in *Escherichia coli* that the time from the initiation of DNA synthesis to cell division is constant at generation times faster than 60 min but at longer generation times there is a change in cell cycle timing controls.

We thank L. H. Hartwell for advice and yeast strains, the Berkeley Yeast Center for yeast strains, and J. Piggott for a gift of α factor. This work was supported by the Medical Research Council of Ireland and Arthur Guinness, Son and Co. Ltd.

Blood flukes have a double outer membrane

THE blood fluke *Schistosoma mansoni* has an unusual tegumental outer membrane which consists of two lipid bilayers^{1,2}. We report here that the double outer membrane is a common feature of the Schistosomatidae (parasites of man which cause schistosomiasis) and also occurs in members of the two other families of blood flukes³, the

Fig. 1 Electron micrographs showing the double outer membrane of representative specimens from each of the three families of blood flukes. *a*, *Schistosoma japonicum* (Schistosomatidae); *b*, *Schistosoma margrebowiei* (Schistosomatidae); *c*, *Aporocotyle simplex* (Aporocotylidae); *d*, *Spirorchis* sp. (Spirorchiidae). ($\times 240,000$).

Aporocotylidae (parasites of fish) and the Spirorchiidae (parasites of turtles). In contrast, flukes (Digenea) belonging to families which inhabit the gut and associated body cavities of the host are limited by a single lipid bilayer. We suggest that the double outer membrane is an adaptation to the intravascular habitat.

Details of the flukes examined and their hosts and locations are presented in Table 1. Specimens were fixed for electron microscopy in glutaraldehyde, osmium tetroxide and uranyl acetate¹, dehydrated in ethanol and embedded in Araldite. Sections were stained with uranyl acetate and lead citrate.

In the Schistosomatidae the double outer membrane was present over virtually the entire surface of both male and female worms; a few small regions of the membrane

had a trilaminar or multilaminar appearance. In the fish and turtle blood flukes two lipid bilayers were found consistently over the whole surface of the parasite. The double outer membrane had the same appearance and identical dimensions in all the blood flukes examined (Table 1, Fig. 1). Each lipid bilayer was approximately 7 nm in thickness and the double outer membrane was 18 nm thick. Some specimens had a layer of diffuse material on the external surface of the double membrane, but we believe that this material originated from the host and did not represent a true glycocalyx. The flukes recovered from environments other than blood had only a single trilaminar outer membrane (single lipid bilayer) approximately 8 nm in thickness (Table 1, Fig. 2). Each of the non-blood flukes had a glycocalyx which varied in appearance from a thin but dense layer in *Fasciola hepatica* to a wide diffuse layer in *Macrocoelium papilliger*.

The advantage conferred by the presence of an additional membrane at the surface of the blood fluke may be related to the fact that any parasite living in the blood vascular system must be constantly exposed to the host's immune defence mechanisms in the form of leukocytes, complement and antibodies. The ability of adult schistosomes to evade the immune response may be due to the host-like antigenic determinants which are found on the worm's surface, and which may prevent the attachment of antibodies against the parasite^{4,5}. The double outer membrane of *S. mansoni* is formed immediately after host penetration^{1,6}, and before host antigens can be detected on the surface of the worm⁷. It has been suggested that the lipid molecules of the outer bilayer may be orientated for the insertion of host glycoproteins or glycolipids⁵. The idea that the two lipid bilayers may differ with respect to their lipid composition is supported by the fact that the outer bilayer is only visualised after uranyl acetate fixation^{1,8}. Rapid turnover and chemical unreactivity of the outer bilayer have also been suggested as possible mechanisms for countering antibody attack⁹. Turnover has been demonstrated *in vitro*⁹, but freeze-fracture studies have shown that most intercalated proteins occur in the outer lipid bilayer²—suggesting that the outer membrane may be more active than the inner membrane.

Table 1 Flukes examined by electron microscopy

Family	Genus and species	Host	Location
(1) Blood flukes			
Schistosomatidae	<i>Schistosoma haematobium</i>	Hamster	Hepatic portal vein
	<i>S. japonicum</i>	Hamster	Hepatic portal vein
	<i>S. matthei</i>	Hamster	Hepatic portal vein
	<i>S. bovis</i>	Hamster	Hepatic portal vein
	<i>S. leiperi</i>	Hamster	Hepatic portal vein
	<i>S. margrebowiei</i>	Hamster	Hepatic portal vein
	<i>S. intercalatum</i>	Hamster	Hepatic portal vein
	<i>S. haematobium</i> ♂	Hamster	Hepatic portal vein
	<i>S. intercalatum</i> ♀	Hamster	Hepatic portal vein
	♂/♀ hybrid	Hamster	Hepatic portal vein
Aporocotylidae	<i>Aporocotyle simplex</i>	Long rough dab	Gill arteries
	<i>A. spinosicanalis</i>	Hake	Heart
Spirorchiidae	<i>Spirorchis</i> sp.	Painted turtle	Pulmonary venule
(2) Non-blood flukes			
Fellodistomatidae	<i>Steringophorus furciger</i>	Cod	Pylorus
Fasciolidae	<i>Fasciola hepatica</i>	Cow	Bile duct
Echinostomatidae	<i>Echinostoma caproni</i>	Mouse	Ileum
Notocotylidae	<i>Notocotylus tricerialis</i>	Chicken	Caecum
Dicrocoeliidae	<i>Dicrocoelium dendriticum</i>	Rabbit	Bile duct
	<i>Corrigia vitta</i>	Field mouse	Pancreatic duct
Acanthocolpidae	<i>Stephanostomum pristi</i>	Cod	Pylorus
Allocreadiidae	<i>Podocotyle atomon</i>	Scorpion fish	Rectum
	<i>Macrocoelium papilliger</i>	Minnow	Stomach
Lepocreadiidae	<i>Lepidopoda elongatum</i>	Cod	Pylorus
Zoogonidae	<i>Zoogonoides viviparus</i>	Dab	Intestine
Hemiuridae	<i>Hemiurus communis</i>	Flounder	Stomach
	<i>Derogenes varicus</i>	Cod	Stomach

Fig. 2 Electron micrographs showing that the outer membrane of flukes recovered from environments other than the blood, consists of a single lipid bilayer. *a*, *Dicrocoelium dendriticum* (Dicrocoeliidae); *b*, *Derogenes varicus* (Hemiuridae); *c*, *Podocotyle atomon* (Allocreadiidae); *d*, *Echinostoma caproni* (Echinostomatidae). ($\times 240,000$).

We conclude therefore, that the double outer membrane is a characteristic feature of the blood flukes, that it consists of two conventional lipid bilayers with differing properties, and that it assists in protecting the parasite against the immunological response of the host.

Macrophages synthesise and release prostaglandins in response to inflammatory stimuli

WHEN macrophages encounter inflammatory stimuli either *in vivo* or *in vitro*, they respond by releasing a number of products which may account for the central role that this cell has in chronic inflammatory diseases¹. These products include hydrolytic enzymes active at neutral² or acidic pH (ref. 1), components of both the classical³ and alternate pathway⁴ of complement, factors modulating responses of lymphocytes to antigens and mitogens⁵, and factor(s) influencing the proliferation⁶ and synthesis of collagen⁷ by fibroblasts. We now show

that macrophages whose phospholipid components were labelled with ³H-arachidonic acid also synthesise and release ³H-prostaglandins (PGs) in response to inflammatory stimuli. These observations are consistent with the findings that human macrophages on intrauterine devices⁸ and guinea pig macrophages responding to lymphokines⁹ release PGs.

It has been shown that tissues such as spleen¹⁰, heart and kidney¹¹, tumour cells¹² and platelets¹³ incorporate radiolabelled arachidonic acid into phospholipids and release labelled PGs. It is known that macrophage phospholipids contain a high proportion of this fatty acid¹⁴. We have found that unstimulated mouse peritoneal macrophages (Fig. 1) exposed to 1 μ Ci ³H-arachidonic acid incorporate approximately 50% of the label into cellular phospholipids within 4 h. Extraction of either stimulated or unstimulated labelled cells showed that the majority of the isotope was incorporated into lecithin with smaller amounts found in phosphatidylethanolamine and triglycerides.

When cultures of unstimulated macrophages are maintained in a serum-free environment for 24 h, less than 3% of the label is released into the culture medium; only a small proportion of this has mobilities identical with standards of PGF_{2α}, PGE₂,

Fig. 1 Zymosan induces a time-dependent synthesis and release of ³H-PGs from unstimulated macrophages. Macrophages were collected from outbred male SW-ICR mice by intraperitoneal lavage with M199 media containing 1% heat-inactivated porcine serum (HIPS) and heparin 20 U ml⁻¹. The cells were plated at 4×10^6 cells per 60-mm dish and incubated for 2 h at 37 °C in 5% CO₂ in air. The non-adherent cells were removed by washing and the adherent cells maintained overnight in M199 plus 10% HIPS. Cellular phospholipids were then labelled by incubating the cells in M199 plus 1% HIPS containing 1 μ Ci ³H-5,6,8,9,11,12,14,15-arachidonic acid (specific activity of 64 Ci mmol⁻¹; New England Nuclear, Boston, Massachusetts) for 4 h. At this time the culture medium was removed, the cells washed twice with 5 ml PBS and incubated in 2 ml M199 devoid of serum with or without sonicated zymosan particles (ICN-K+K Labs, Plainview, New York). The stock zymosan preparations were washed and sterilised by boiling three times in PBS. The medium was removed, acidified to 0.03 M with citric acid, authentic standards added, and extraction carried out using the method of Folch. The combined organic phases were dried and chromatographed on SG81 paper (Whatman) with ethyl acetate-acetone-acetic acid (90:10:1). The standard PGE₂ and PGF_{2α} were visualised using iodine vapour, the corresponding area cut out and the radioactivity corresponding chromatographically with PGE₂ and PGF_{2α}/6KF_{1α} determined. $n = 3 \pm$ s.d. Open columns, control cultures; hatched cultures exposed to zymosan 50 μ g per culture. Left two columns in each set of four, PGE₂; right two, 6KF_{1α}.

PGD₂ and PGA₂. When, however, such cultures are exposed to an inflammatory agent, zymosan, they synthesise and release large amounts of ³H-PGs in a time-dependent manner. Significant increases in synthesis and release are observed as early as 30 min after addition of zymosan, continuing thereafter for at least 24 h (Fig. 1). In the separation system described in Fig. 1, two major peaks of radioactivity were found. The first of these peaks had the same mobility as authentic PGE₂. This identification is supported also by radioimmunoassay and by its conversion to PGB₂ on base hydrolysis (R.J.B. *et al.*, unpublished). The second of these peaks had the same mobility as PGF_{2α} and 6-keto PGF_{1α} (6KF_{1α}) which are not separable in this system. Using a second chromatographic system, ethyl acetate-acetic acid, 99:1, which separates these two components, the second radioactive peak has, however, been tentatively identified as 6KF_{1α}. ³H-thromboxane B₂ (TXB₂) does not seem to be a major product of ³H-arachidonic acid from unstimulated macrophages exposed to zymosan.

Macrophages from mice stimulated with thioglycollate broth—a sterile inflammatory agent—have a greatly diminished capacity for synthesising and releasing ³H-PGs in response to increasing amounts of zymosan, compared with cells from unstimulated mice, although both cell populations incorporated approximately the same amount of ³H-arachidonic acid (Fig. 2). At the lowest dose of zymosan tested (10 µg per plate), unstimulated cells showed a fivefold increase in ³H-PGE₂ and a 2.5-fold increase in ³H-6KF_{1α} release. At 200 µg ml⁻¹ zymosan, unstimulated cells showed a 24-fold increase in ³H-PGE₂ and a 15-fold increase in ³H-6KF_{1α} release. On the other hand, cells from thioglycollate-stimulated mice showed only a fivefold increase in ³H-PGE₂ and a 2.5-fold increase in ³H-6KF_{1α} release in response to 200 µg zymosan per plate. In the absence of zymosan, both unstimulated and stimulated cells release similar small amounts of ³H-PGE₂ and ³H-6KF_{1α}. Cells from stimulated or unstimulated mice cultured in the absence or presence of zymosan remained intact as judged by morphological examination and the retention of the cytoplasmic marker enzyme, lactate dehydrogenase.

The synthesis and release of ³H-PGs by unstimulated macrophages exposed to zymosan can be completely inhibited by indomethacin (Fig. 3). The effect of this cyclo-oxygenase inhibitor on ³H-PGs synthesis in this system is a potent one, dose-response experiments showing an ID₅₀ of 2×10^{-8} M.

Fig. 2 Thioglycollate-induced macrophages synthesise and release less ³H-PG than unstimulated macrophages in response to zymosan challenge. *a*, PGE₂; *b*, 6KF_{1α}. Unstimulated macrophages and macrophages obtained from mice injected with 2 ml thioglycollate broth (BBL, Cockeysville, Maryland) 4 d previously were cultured and labelled as described in Fig. 1. The radiolabelled cells were then incubated with varying concentrations of zymosan for 4 h. The released radiolabelled PGs were measured as described in Fig. 1. The stimulated cells (●) incorporated 47% of the ³H-arachidonic acid; the unstimulated cells (○) incorporated 57% of the ³H-arachidonic acid. Control cultures of the stimulated cells without zymosan addition contained 365 ± 139 c.p.m. as PGE₂ and 191 ± 12 c.p.m. as 6KF_{1α}; control cultures of the unstimulated cells contained 228 ± 31 c.p.m. as PGE₂ and 102 ± 17 c.p.m. as 6KF_{1α}. $n = 3 \pm$ s.d.

Fig. 3 Zymosan but not latex stimulated ³H-PG synthesis and release from unstimulated macrophages. Unstimulated macrophages were cultured and labelled as described in Fig. 1. The release incubation period was 4 h. Suspensions of latex beads 0.8 µm; (Dow, Indianapolis, Indiana) were sonicated before addition. The numbers in the histogram indicate percentage stimulation over control. $n = 3 \pm$ s.d. Left-hand column in each pair, PGE₂; right-hand, 6KF_{1α}.

PG synthesis does not always accompany phagocytosis by macrophages. Fig. 3 shows that unstimulated macrophages exposed to a large amount of latex particles do not release ³H-PGs above control levels. Examination of cultures by phase contrast microscopy showed that these particles had been phagocytosed. It is noteworthy that latex lacks the ability to induce chronic inflammation¹⁵.

These findings complement those of Glatt and Brune who have used other stimuli to induce release of PGE₂ by mouse peritoneal macrophages¹⁶. In addition, we have unpublished data showing that macrophages release PGs in response to other inflammatory stimuli such as asbestos and antigen-antibody complexes. Clearly, PGs are now established as products of macrophages responding to inflammatory stimuli. The tentative identification 6KF_{1α} as being a major secretory PG by zymosan-induced macrophages remains to be confirmed. Our data, however, suggest that the potent biologically active precursor, PGI₂, which has been shown to be released by cells of the vascular endothelium¹⁷, may also be released by macrophages. The contribution of PGs released by macrophages to the diverse functions of this cell remains to be elucidated.

We thank Dr E. A. Ham for 6KF_{1α} and TXB₂ standards.

Primary *in vitro* sensitisation of human T cells

METHODS for the *in vitro* development of primary immune responses have been crucial for the understanding of mechanisms of cooperation between T and B cells and between T cells and macrophages¹⁻³. Few efforts to date have been reported for primary *in vitro* sensitisation of human lymphocytes, most of which have involved sensitisation to allo- or xeno-antigens⁴⁻⁶ or plaque-forming responses to sheep red blood cells (SRBC)^{7,8}. Development of killer T cells against HLA-identical⁹, or autochthonous tumour cells^{10,11} have usually required coculture with third party allogeneic cells for development of cytotoxicity. Given the ethical constraints on *in vivo* studies of human T-cell function, and noting the development for the first time of a system for the sensitisation of guinea pig T cells *in vitro* to a variety of antigens¹², we were encouraged to develop an *in vitro* system for the priming and boosting of human T cells to well defined haptenic determinants without the requirement for a third party cell.

We chose trinitrophenol (TNP) as antigen for two reasons: in our hands it elicits the best response; and second, animal studies show that when recognised in conjunction with Ia antigens on macrophages, TNP can elicit helper-type T cells¹², and when recognised simultaneously or as an antigenic complex with H-2 K and D antigen can generate killer T cells¹³. The hapten TNP, therefore, has the potential in the human system to serve as a model for primary *in vitro* sensitisation and recognition of altered self.

Tonsil or peripheral blood cells were divided into two portions (Fig. 1). The responder cell population was purified by nylon wool column fractionation; the stimulator population, unfractionated, was treated with mitomycin C or X-ray irradiation and either conjugated with TNBS (trinitrobenzene sulphonate) or left unconjugated as control. Optimum culture conditions required 5×10^6 responder cells plus $1-5 \times 10^6$ stimulator cells in 2 ml of RPMI-1640 containing 10% AB serum and antibiotics. Cultures were fed twice during the 7-d priming. Boosting was done in microtitre plates on day 7 using autochthonous booster cells prepared exactly as were the stimulator cells. Boosting of peripheral blood cells was done with freshly drawn blood; boosting of tonsil cells was done with cells that had been cryopreserved. Cultures did not require 2-mercaptoethanol or rocking (forward and backing tilting during 37 °C incubation). Responses were measured by incorporation of labelled thymidine (³H-TdR), the virus plaque assay and cytotoxicity.

Figure 2 indicates the kinetics of proliferation in the priming and boosting cultures. Nylon wool purified cells alone showed very little proliferation during culture. The addition of mitomycin-treated TNP-coupled or uncoupled cells caused measurable proliferation between days 3 and 5. Optimum boosting conditions required cells primed for at least six and preferably seven days, when background

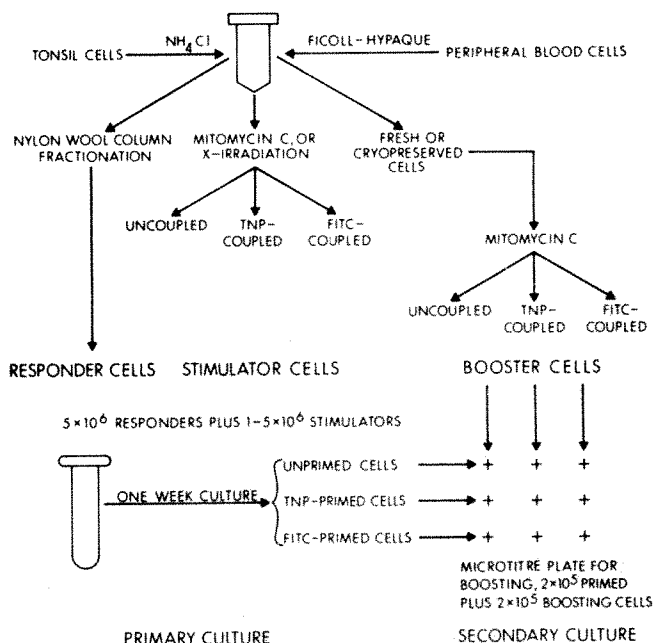

Fig. 1 Schematic representation of the procedure for priming and boosting of T cells to hapten-coupled autochthonous cells. Tonsil cells, after NH_4Cl lysis of red cells or peripheral blood mononuclear cells after Ficoll-Hypaque density centrifugation, were divided into two portions. The first was passed over nylon wool columns for preparation of T cells¹⁴. This gave a population containing fewer than 2%-3% Ig+ cells by immunofluorescence. The second unfractionated population was treated with mitomycin C ($50 \mu\text{g ml}^{-1}$, 37 °C, 30 min) or X-ray irradiation (500 rad), and hapten-conjugated or left unconjugated as control. A portion of tonsil cells was cryopreserved in 10% dimethyl sulfoxide-20% foetal calf serum in RPMI under liquid nitrogen until needed for the secondary (boosting) culture. TNP-coupling with 10-mM TNBS in phosphate-buffered saline (PBS) pH 7.4 was done according to Shearer¹⁵, and FITC-coupling was carried out with $100 \mu\text{g}$ FITC per 10^8 cells per ml in PBS pH 9.0 (ref. 16). Primary cultures were set up in 16×125 -mm tissue culture tubes containing 5×10^6 responder and an equal number of stimulator cells in 2 ml of RPMI 1640 containing 10% AB serum, 8 mg per 100 ml gentamycin, 40 units ml^{-1} mycostatin, $100 \mu\text{g ml}^{-1}$ streptomycin and extra glutamine, 2 mM. Primary cultures were fed twice, on days 2 and 5, and kept in a humidified atmosphere of 5% CO_2 , 95% air. Secondary boosting cultures were set up on day 7 with 2×10^5 viable primed cells plus 2×10^5 boosting cells per 0.2 ml in microtitre plates. Boosting cells were prepared as described for stimulator cells using thawed unfractionated tonsil cells or freshly drawn and prepared peripheral blood mononuclear cells. At 16 h before cell collection $1 \mu\text{Ci}$ ³H-TdR (specific activity 3 Ci mmol^{-1}) was added to each well. Cultures were collected on glass fibre filters, placed in scintillant (NEN 950A) and counted in a Beckman liquid scintillation counter. All determinations were done in triplicate.

proliferation had largely ceased. Boosting of TNP-primed cells with TNP-coupled autochthonous cells resulted in a marked and rapid proliferation of the primed cells between 24 and 96 h after boosting; unprimed cells showed no response (Fig. 2).

The boosted response is antigen specific, as shown in Table 1. T cells from each tonsil were primed to either TNP-cells or FITC-cells. After 1 week both cultures were boosted with both antigens. TNP-primed cells responded to TNP-cells and not to FITC cells, whereas FITC-primed cells responded to FITC cells and not to TNP cells. In 14 experiments, TNP-primed cells gave a mean value above background of $14,765 \pm 3,199$ c.p.m. and a mean stimulation index of 7.0 ± 1.6 when boosted with TNP cells. In five experiments, the response of the FITC-primed cells was always less than the response of TNP-primed cells; the mean incremental ³H-TdR incorporation was $3,743 \pm 2,330$ c.p.m. and the stimulation index was 3.18 ± 1.1 . Ultraviolet light microscopy revealed that the stimulating and boosting cells were coupled with FITC at the

Fig. 2 Time course of incorporation of ^3H -TdR in primary (sensitisation) cultures of 5×10^6 nylon wool cells alone (\square), 5×10^6 nylon wool purified cells plus 5×10^6 uncoupled stimulator cells (control) (\triangle), and after; TNP-boosting (\blacktriangle), and 5×10^6 nylon wool purified cells plus 5×10^6 TNP-coupled autochthonous cells (\circ), and after TNP-boosting (\bullet). The TNP-primed and unprimed cultures were each boosted on day 7 (arrow) with TNP-coupled autochthonous cells, as indicated. S.e.m. is indicated for boosted cultures; for priming cultures, standard errors were always less than 20%.

initiation of culture, and their viability at this time was comparable with that of TNP-coupled cells, that is, greater than 90%.

The response of peripheral blood cells to TNP was usually less than the response given by tonsil T cells (Table 1). In four experiments, three individuals responded (Table 1, and data not shown) while one was completely refractory. Whether this is as a result of individual differences in responder, suppressor or antigen presenting cells types has yet to be determined. To date, we have not been able to achieve a significant *in vitro* response of peripheral blood cells to FITC.

Cultures of T cells plus mitomycin-C treated autochthonous uncoupled cells usually showed a low proliferative response during the priming culture (Fig. 2), as did the T cells cultured together with TNP-coupled cells. When such unprimed control cells were 'boosted'

with uncoupled stimulator cells, the incorporation of ^3H -TdR increased from 2- to 12-fold as compared with their proliferative response when cultured alone (Fig. 2 and Table 1). This seems most consistent with the experiments of Kuntz *et al.*¹⁷, who were able to demonstrate, in humans, a response of purified T cells to autochthonous B and K cells peaking about day 6, though no attempt was made to boost these cells.

The response of primed cells to concanavalin A (con A) was included in all experiments to serve as an internal reference for the relative magnitude of the boost. The response to TNP-cells was in the range of 50% of the con A response. (Table 1).

Viable stimulating cells were required for effective sensitisation. Stimulator cells treated at 56°C for 30 min functioned poorly compared with viable stimulator cells; the response to boosting was only one sixth that of cultures primed with viable cells (data not shown).

We have attempted to estimate the number of antigen-reactive T cells in the boosted cultures using the virus plaque assay¹⁸. Table 2 shows the results of these experiments. The background response was low in all three controls, allowing the detection in specifically boosted cells of approximately one cell per thousand plated. This is a sevenfold increase over primed cells not boosted, and a 50-fold increase over unprimed cells boosted with TNP-cells. These data suggest that the initial number of TNP-reactive cells at day 2 of priming must be relatively low, certainly less than 20 per 10^6 cells. But, one cell in 10^5 in boosted cultures is considerably less than 10–60 per 10^5 cells activated by con A or allogeneic cells^{19,20}, although about 10-fold greater than the number of pre-killer cells activated to TNP in a recently reported murine syngeneic cytotoxicity assay²¹. This may reflect the existence of fewer potentially hapten or self-reactive than allo-reactive clones.

We have attempted to detect a preference on the part of the primed cell for restimulation with TNP coupled to autochthonous cells relative to allogeneic cells. To obviate the problem of allogeneic stimulation, we have taken advantage of the finding that significant stimulation of ^3H -thymidine incorporation can be obtained 24 h after boosting (Fig. 2) when little or no MLR is seen ($\text{SI} < 2.0$). In three experiments, a mean increase of $4,122 \pm 764$ c.p.m. above background was obtained after boosting with TNP-coupled autochthonous (priming) cells, while boosting with TNP-coupled allogeneic cells resulted in a decrease of 27 ± 308 c.p.m. As has been demonstrated in animal models^{22,25}, these results indicate that there is likely to be a restriction on the restimulation of primed T cells to antigen presentation on the priming cell type. Taken together with the requirement for a viable cell for effective antigen presentation, it seems likely that in this system, T cells recognise hapten in conjunction with

Table 1 Response of *in vitro* primed tonsil and peripheral blood T cells to hapten-coupled autochthonous cells

Expt no.	T cells from:	Primed to:	Boosting cell type added, day 3 response (c.p.m.)								Con A
			None	Uncoupled	TNP cells	Δ c.p.m.	SI	FITC cells	Δ c.p.m.	SI

SI=Stimulation index

Fig. 3 Virus PFU were determined as for Table 2. *a*, 0.7; *b*, 0.1 and *c*, 1.9 viral plaque-forming cells per 10^5 cells. *a*, TNP-boosted, not primed; *b*, TNP-primed, not boosted; *c*, TNP-primed and boosted. $^3\text{H-TdR}$ incorporation was determined as for Table 1. Cytotoxicity assay was performed in triplicate in round bottom microtitre wells containing 3×10^5 effector cells and 3×10^3 ^{51}Cr labelled targets in 0.2 ml. For preparation of target cells 15 μl of 1:100 diluted phytohaemagglutinin P (DIFCO) was added to 2×10^6 tonsil cells in 2 ml of medium 3 d before assay. On day of assay, targets were labelled with $\text{Na}^{51}\text{CrO}_4$ (Amersham/Searle, 1 mCi ml^{-1}), 250 μCi in 0.4 ml per 15×10^6 cells for 2 h at 37°C . Cells were washed three times and either left uncoupled or coupled with TNBS¹⁵. Effectors plus targets were incubated at 37°C for 16 h after which plates were centrifuged and 0.1 ml was collected and counted in an LKB model 80000 gamma counter. Spontaneous release values for TNP-coupled and uncoupled targets were the same, 47% of total releasable counts as determined by three cycles of freezing and thawing; all assays were performed on the tenth day of culture (day 3 after boosting).

membrane determinants. In the mouse system, Forman has shown that TNP couples directly to H-2 antigens on the cell surface, and that they, most likely, are the site of recognition by prekiller T cells^{26,27}. It will be of obvious interest to determine whether HLA antigens are involved in the recognition of TNP in the present system, and if so, whether there is any consistent restriction like that seen with cytotoxic T cells generated against Y antigen²⁸. On the other hand, the ability of primed T cells to discriminate effectively between TNP and FITC is compatible with the view that some T cells may primarily recognise hapten, a view supported by several studies in experimental animals²⁹⁻³¹.

Table 2 Enumeration of activated T cells primed and boosted *in vitro* by virus plaque assay

Boosting cell	Assay	Tonsil T Cells	
		Unprimed	TNP-primed
Uncoupled cells	$^3\text{H-TdR}$ incorporation	20,624 \pm 1,171	6,503 \pm 875
	V-PFC/ 10^5 Cells	0.045 \pm 0.001	0.15 \pm 0.01
TNP-coupled cells	$^3\text{H-TdR}$ incorporation	12,481 \pm 414	49,153 \pm 1,174
	V-PFC/ 10^5 Cells	0.02 \pm 0.002	1.02 \pm 0.23

Assay for virus plaques was performed 40 h after boosting. Values are arithmetic means \pm s.e.m. V-PFC, virus plaque-forming cells.

Attempts were made to ascertain whether specific cytotoxic T lymphocytes (CTL) could be generated. The data presented in Fig. 3 indicate that CTL capable of killing TNP-coupled targets are generated from naive human T cells after *in vitro* priming and boosting with TNP-coupled autochthonous cells. No CTL were detectable in cultures that were primed but not boosted, or not primed and

'boosted'. In contrast with results obtained in the mouse system¹⁵, CTL were not found in primary cultures, but only in restimulated cultures. It is unclear whether CTL in man are developed on first exposure to antigen but at undetectable levels, or whether a further differentiative step requiring restimulation is necessary. It will also be of interest to clarify the nature of the antigen-presenting cell(s) in this system.

Genetic non-responsiveness of murine fibroblasts to bacterial endotoxin

LETHAL infections with Gram-negative bacteria are thought to be due in large part to the toxicity of cell wall lipopolysaccharide (endotoxin). The mechanisms of action of lipopolysaccharide (LPS) have recently been clarified by *in vitro* studies which have helped explain many of the pathophysiological sequelae of endotoxin exposure^{1,2}. C3H/HeJ mice, which are genetically resistant to many of the effects of endotoxin, have proved a valuable model for the systematic investigation of endotoxin-mediated phenomena³⁻⁵. Bacterial endotoxins are able to interact

in vitro with a variety of cells and serum factors^{1,2,6} and it is known that LPS acts on murine B lymphocytes as a polyclonal activator for both mitogenesis and immunoglobulin synthesis⁷. This function has been found to be deficient in the C3H/HeJ mouse^{3,4}. Also, endotoxins activate macrophages⁸⁻¹⁰, and this function also seems to be deficient in C3H/HeJ mice⁵ (Ryan, J. L., Glode, L. M. and Nathan, C. F., unpublished observations). To determine if the C3H/HeJ genetic defect in responsiveness to endotoxin is more general, we have investigated the ability of bacterial endotoxin to stimulate C3H/HeJ embryonic fibroblasts. Fibroblasts were chosen because it has recently been shown that they are endotoxin sensitive cells¹¹.

To measure responsiveness of fibroblasts to LPS, we have assayed their rate of glucose utilisation in culture. This has previously been shown to be a sensitive assay for LPS-induced activation of spleen cells and peritoneal cells (Ryan, J. L. *et al.*, unpublished observations). Fibroblasts were isolated from 12-14 d C3H/HeJ and C3H/HeN embryos by removing the head, extremities, and liver, and mincing the remaining tissue with forceps before incubating with BSS and trypsin-EDTA for 10 min each. The tissue was further incubated with trypsin-EDTA for 20 min and the resulting cell suspension filtered through nylon gauze. These filtered cells were cultured at a density of 10^6 per 10 ml in 100-mm plastic tissue culture dishes using Dulbecco's modified MEM with 10% FCS. Cultures were collected with trypsin and transferred to new plates every 5-7 d.

To measure glucose utilisation, 5×10^4 fibroblasts which had been passed at least once were plated in flat-bottomed microtitre plates. This number of embryonic fibroblasts forms almost a complete monolayer in the wells once the cells have spread. Two types of LPS were used to stimulate the cultures. Both were derived from *Escherichia coli* K235, one by phenol extraction¹² and the other by butanol extraction¹³. It has previously been shown that butanol-extracted K235 LPS contains protein tightly bound to the lipid A moiety which activates C3H/HeJ spleen cells. This protein is not present in phenol-extracted K235 LPS which is thus unable to activate C3H/HeJ lymphocytes while having the ability to activate C3H/HeN lymphocytes normally^{14,15}.

The rate of glucose utilisation by C3H/HeJ and C3H/HeN fibroblast cultures stimulated by K235 LPS is shown in Table 1. These data show that glucose utilisation can be used to measure responsiveness of murine fibroblasts to LPS and that C3H/HeJ fibroblasts are not

Table 1 Rate of glucose utilisation by C3H/HeJ and C3H/HeN fibroblast cultures stimulated by K235 LPS

LPS	C3H/HeN (nmol glucose used per 24 h)	C3H/HeJ (nmol glucose used per 24 h)
None	384 ± 8.0	148 ± 2.0
Phenol K235	502 ± 18	144 ± 4.0
Butanol K235	574 ± 32	264 ± 2.0

The glucose content of 10- μ l aliquots of culture supernatant was determined enzymatically during a 2-3-d culture period. Each value represents the total glucose used over an average 24-h period by a culture of 5×10^4 fibroblasts. Values are means \pm s.e.m. of triplicate cultures. The amount of glucose in each aliquot was determined by adding 0.9 ml of the enzyme mixture to each 10- μ l aliquot, mixing vigorously and reading the A_{340} after a 2-min equilibration time. The enzyme mixture was composed of 0.7 ml buffer (0.1 M Tris, 0.064 M NaCl, 3.5 mM MgCl₂, 0.15 mM CaCl₂, pH 7.5) (ref. 21), 0.1 ml 20 mM ATP, 0.1 ml 5 mM NADP and 5 μ l of a mixture of hexokinase and glucose 6-phosphate dehydrogenase (250 U ml⁻¹ hexokinase). The mixed enzymes were obtained from Sigma Chemical (St Louis, Missouri). Both types of LPS were added to a final concentration of 10 μ g ml⁻¹. Cultures were carried out in flat-bottomed microtitre plates using 200 μ l Eagles MEM supplemented with glutamine 1 mM, streptomycin 10 μ g ml⁻¹, penicillin 100 U ml⁻¹, and gentamycin 25 μ g ml⁻¹. LPS was the gift of Dr D. C. Morrison, Scripps Clinic, La Jolla, California.

Fig. 1 The upper graph shows the amount of glucose remaining in cultures of C3H/HeN (continuous line) and C3H/HeJ embryonic fibroblasts (dotted line) after stimulation by different concentrations of butanol K235 LPS compared with unstimulated cultures. The lower graph shows similar data for cultures stimulated by phenol K235 LPS. Each point represents the mean of glucose assays from triplicate cultures \pm s.e.m. Culture conditions and glucose assays were as described previously. Measurements on C3H/HeN fibroblasts were made after 32 h of culture, whereas those on C3H/HeJ fibroblasts were made after 66 h of culture, to equate the total glucose utilisation by both cultures at the 50% level. ---, C3H/HeJ; —, C3H/HeN.

responsive to phenol K235 LPS, whereas they are responsive to butanol K235 LPS ($P < 0.01$). In addition, it seems that approximately equal numbers of the C3H/HeJ fibroblasts use glucose at a lower rate than C3H/HeN fibroblasts in both the presence and absence of LPS. The significance of the lower baseline rate of glucose utilisation in C3H/HeJ fibroblasts is not explained, but a similar phenomenon has been observed for C3H/HeJ macrophages (Ryan, J. L. *et al.*, unpublished observations).

A dose-response curve for both types of LPS in C3H/HeJ and C3H/HeN fibroblast cultures is shown in Fig. 1. As seen in the upper graph, both strains respond well to butanol LPS. The lowest dose at which a significant response can be measured is 0.5–5 μ g ml⁻¹ ($P < 0.01$) LPS for the butanol-extracted material. Activation by phenol K235 LPS is shown in the lower graph. In this case the C3H/HeJ fibroblasts are not stimulated at any of the doses tested ($P < 0.001$), whereas the C3H/HeN fibroblasts are stimulated at a dose of 50 μ g ml⁻¹ LPS ($P < 0.01$), which is at least 10-fold lower than the concentration of butanol LPS required for activation. This suggests that the protein present in the butanol LPS may in fact be blocking the activity of the lipid A moiety. Modulation of the biological activities of lipid A by protein associated with lipid A has been suggested¹⁶ and these data seem to corroborate those conclusions.

C3H/HeJ non-responsiveness to LPS has been demonstrated in B lymphocytes^{3,4}, macrophages⁵, and now in embryonic fibroblasts. This finding suggests that there is a global cellular defect in the ability of the C3H/HeJ mouse to respond to highly purified LPS. It has also been shown in many laboratories that C3H/HeJ mice are very resistant to the lethal effects of intravenous LPS having an LD₅₀ of 3,000 μ g, whereas normal mice usually have an LD₅₀ of 200–500 μ g LPS (ref. 17).

We may conclude that activation of LPS-sensitive cells may have a critical role in mediating the lethal effect of intravenous LPS (ref. 17). It must be recognised, however, that this non-responsiveness of C3H/HeJ mice to LPS does not seem to protect them from death due to infection with Gram-negative bacteria¹⁷⁻¹⁸. Thus, it is evident that there are factors other than LPS which contribute to the toxicity of Gram-negative bacteria. The role of cell wall lipoprotein in mediating toxicity is only beginning to be defined²⁰. Studies using LPS non-responder mice should permit a better understanding of the function of non-LPS cell wall material in producing the pathophysiological effects of endotoxin.

Density-dependent inhibition of fibroblast growth is overcome by pure mitogenic factors

CELL density is of interest because it may have a critical role in the regulation of growth, development, and in malignant transformation. In cell culture, crowding slows and eventually stops cell proliferation of a variety of cells maintained on a solid surface¹⁻⁵. This property is usually lost after malignant transformation¹⁻⁵. Two major hypotheses have evolved to explain this phenomenon. The contact inhibition hypothesis holds that specific surface receptors are activated by cell-cell contact and generate a negative signal which halts further growth¹⁻³. The humoral hypothesis proposes that high cell density limits the availability of medium components, particularly of growth factors present in serum^{4,5}. Although much experimental evidence has been adduced in support of the humoral hypothesis, most experiments in which the effect of cell density on growth has been thoroughly investigated were performed in the presence of whole serum as the source of growth factors. The chemical complexity of serum leaves open the possibility that some of its effects may be exerted by molecules that interfere with inhibitory cell-cell contacts. Thus, definitive evidence for a humoral hypothesis in growth regulation in culture is still lacking. To circumvent this objection we have examined the effect of cell density in a model system in which chemically defined molecules rather than whole serum stimulate DNA synthesis and cell division in sparse or crowded cells arrested in G₀/G₁. We report here that density dependent inhibition of fibroblast growth is overcome by pure mitogenic factors.

Epidermal growth factor (EGF) and insulin, added at low concentrations dramatically stimulate DNA synthesis in 3T6 cells maintained in serum-free Dulbecco's modified Eagle's medium (DEM) supplemented with vitamin B₁₂ (ref. 6). To establish whether the response of the cells to constant concentrations of EGF and insulin is dependent on the cell density of the culture, cell suspensions were plated at different densities, arrested in G₀ by limitation of serum and then exposed to factors and ³H-thymidine for 26 h (Fig. 1). The labelling index is optimal at a density of approximately 2 × 10⁴ cells cm⁻² but strongly decreases at higher concentrations where extensive cell contacts take place. Figure 1 also shows that EGF and insulin stimulate DNA synthesis at low densities (0.5 × 10⁴ cells cm⁻²) where only 5% of the available surface is occupied by 3T6 cells and very few cells in close contact are observable microscopically. This renders unlikely the possibility that the pure peptides act by diminishing inhibitory cell-cell contacts. Thus the striking dependence of stimulation on cell density raises the possibility of investigating this phenomenon in chemically defined conditions rather than in the presence of serum.

Fig. 1 Effect of cell density on the stimulation of cultures of 3T6 cells into the S-phase by EGF and insulin. Cultures were exposed to 1 ng ml⁻¹ EGF, 100 ng ml⁻¹ insulin, 400 ng ml⁻¹ vitamin B₁₂ and ³H-thymidine (4 µCi ml⁻¹ 0.2 µM) in DEM for 26 h. They were then fixed for autoradiography. Each solid circle represents the mean of two separate determinations (deviation not greater than 5%). Control dishes (B₁₂ containing DEM alone) pooled from a number of experiments are shown by open circles. Stock 3T6 cells were passaged at 3-d intervals in DEM containing 10% foetal calf serum (FCS), 100 U ml⁻¹ penicillin and 100 ng ml⁻¹ streptomycin in a 10% CO₂ atmosphere at 37 °C. In all experiments cell suspensions were plated in Nunc dishes at the appropriate density in 0.5% FCS-DEM, and kept for at least 5 d; they were then washed twice in DEM and left in serum-free medium for 2 d before use. The cell density (abscissa) represents the density at the end of the experiment.

A critical prediction of the humoral hypothesis is that raising the concentrations of the same pure factors that support growth in sparse cultures should overcome the inhibition of growth characteristic of high-density cultures. To test this prediction we determined the dose response for stimulation of DNA synthesis by EGF and insulin in cultures prepared at two different cell densities, sparse and dense (Fig. 2). EGF is more mitogenic in sparse than in dense cultures. Thus EGF, in the absence of insulin stimulates 60% of the cells blocked in G₀ at low density to enter into the S-phase of the cell cycle (Fig. 2a), while it only stimulates 30% of the cells of the denser culture (Fig. 2b). In turn, insulin stimulates DNA synthesis in sparse cultures, even in the absence of EGF and markedly enhances the response to EGF in both sparse and dense cultures. The salient feature of Fig. 2 is that a high concentration of factors is capable of maximally stimulating DNA synthesis in the dense cultures. Essentially similar results were obtained when incubation time was 24 instead of 48 h and also when the total ³H-thymidine incorporated, rather than the labelling index, was measured. The data indicate

Fig. 2 Dose response to EGF at various insulin concentrations for two different cell densities: *a*, 3.0×10^4 cells cm^{-2} ; *b*, 6.5×10^4 cells cm^{-2} . Insulin concentrations: ●, zero; ▲, $0.1 \mu\text{g ml}^{-1}$; ■, $1 \mu\text{g ml}^{-1}$; ◆, $10 \mu\text{g ml}^{-1}$. Cultures were exposed to mitogens and ^3H -thymidine for 48 h and fixed for autoradiography.

that high levels of factors overcome the density dependent inhibition of growth.

To further substantiate this conclusion we investigated the effect of cell density on the ability of stimulated cells to complete the cell cycle and divide. Cultures were prepared at two different densities (3.3×10^4 and 17.4×10^4 cells cm^{-2}), arrested in G_0 and then exposed to factors at low and high concentrations for 72 h. At the end of the incubation the number of cells per culture was determined. Table 1 shows that both concentrations of factors stimulate an increase in cell number (70%) in sparse cultures. In contrast, only the combination of factors at high concentrations is able to produce a comparable increase in the crowded cultures. This result, together with the autoradiographic data clearly demonstrates that the growth block imposed by high cell density can be overcome by using appropriate levels of pure factors.

We considered the possibility that the ability of high

Table 1 Effect of cell density on growth

EGF (ng ml^{-1})	Insulin ($\mu\text{g ml}^{-1}$)	Cell density (cells $\text{cm}^{-2} \times 10^{-4}$)	
		Sparse	Dense
—	—	2.5	13.3
1	0.2	5.6	14.8
10	5.0	5.4	24.1

Cells were plated at two densities in 50-mm Nunc dishes and arrested in G_0/G_1 before exposure to factors. Cell densities before exposure were 3.3×10^4 and 14.7×10^4 cells cm^{-2} for sparse and dense cells respectively. Two levels of factors were used. After 72 h incubation, cells were removed by trypsinisation and counted with a Coulter counter. In sparse cultures for each determination six dishes were divided into two groups of three pooled dishes. In dense cultures nine dishes were divided into three groups of three pooled dishes. Three aliquots of each group were counted. Data are mean group values. Group duplicates and triplicates did not vary by more than 15% and in general were below 7.5%.

levels of insulin to potentiate the effect of EGF in crowded cultures may be due to a mechanism of action unrelated to its hormonal effect, such as the mild proteolytic activity reported to be associated with the pure hormone and with the B chain of the molecule⁷. We found several lines of evidence that exclude this possibility in our system: (1) The purified B chain of the insulin molecule does not replace the hormone in stimulating the entry of sparse or dense cultures into S. (2) The B chain, added with sufficient amounts of insulin and EGF to stimulate low density cultures, does not overcome the density block in crowded cells. (3) Ovomucoid ($100 \mu\text{g ml}^{-1}$) and soybean ($50 \mu\text{g ml}^{-1}$) trypsin inhibitors which were reported to suppress the proteolytic activity of insulin⁷, do not prevent the enhancing effect of high concentrations of insulin. Furthermore, we verified that the preparation of insulin used in our studies yields a single band (molecular weight 6,400) when analysed in sodium dodecyl sulphate-polyacrylamide gel electrophoresis. In addition zinc, which is present in the insulin preparation and has been shown to promote growth⁸ is completely inactive when tested at 6×10^{-8} M and 6×10^{-7} M in the presence and absence of factors. All these experiments indicate that in crowded cultures as in sparse ones, the action of insulin is related to its metabolic effects mediated by specific surface receptors.

Our results emphasise that chemically defined growth promoting factors used in *in vitro* systems can overcome the restriction of growth imposed by high cell density. These findings have two interesting implications. First, the use of two pure peptides instead of a complex substance like serum for overcoming the block imposed by high cell density removes a major objection in accepting a humoral rather than a contact hypothesis for regulation of growth. The possibility remains that the pure peptides act by diminishing contact inhibition but this seems unlikely because the factors are effective at low cell densities (Fig. 1). Second, the fact that cells transformed by some RNA tumour viruses have an alteration in the EGF growth regulatory mechanisms⁹, that cultures of BHK cells transformed by SV40 viruses produce growth promoting polypeptides¹⁰ and our finding that defined peptides can release cells from density dependent inhibition of growth suggest that growth factors may have a critical role in modulating normal and abnormal cell proliferation.

Cultured human breast cancer cells lose selectivity in direct intercellular communication

VARIOUS small molecules, up to 1,600 molecular weight¹, can pass directly between certain animal cells in contact, probably through gap junctions^{2,3}. Such communication

When you're studying cyclic nucleotides and you don't know which way to turn

We understand that when you are working in the cyclic nucleotide area, the subject is so diverse and so complex that you don't want to have to worry about the problems of accurate measurement.

So we would like to take a little weight off your mind and offer you our two kits in this field.

Cyclic AMP and Cyclic GMP.

Both of the tests are simple, accurate and will take you about four hours from start to finish.

So it's not surprising that you can carry on with your research and leave the problems of accurate measurement to us.

You know where you are with our Cyclic AMP & GMP kits

may partly mediate growth control in multicellular organisms and cultured cells, so that disturbances in the normal pattern of communication could be related to malignant growth^{4,5}. The ³H-nucleotide transfer method⁶, based on metabolic cooperation⁷ has shown that communication is not always an all-or-none phenomenon, but may be selective^{8,9}. For example, human mammary epithelial cells from benign tumours or milk do not communicate with human breast fibroblasts (HumF), although either type can communicate well with homologous cells. We have examined the communication between cancer cells from several human breast cancer sources and found that, unlike normal

mammary epithelium, they do not show selectivity in communication. The cancer cells fall into one or other of the two functional groups we have defined as non-selective communicators (communicate with all cells capable of communication) or non-communicators (unable to communicate with homologous or heterologous cells) suggesting that the change to malignancy involves some change in the pattern of cell communication.

The breast cancer cells were either established lines derived from malignant pleural effusions, or primary cultures obtained by the 'spillage' technique¹⁰, from surgical specimens¹¹. Two established lines, MCF-7 (ref. 12) and MDA-157 (ref. 13), and three primary cultures, T162, T231 and T235, were examined. The putative cancer cells which are obtained from primary and metastatic carcinomas by the spillage method, we have called HumE¹ (ref. 11). These cells have a low labelling index (less than 2% in 48 h), but metabolise and can incorporate 5-³H-uridine into their nucleotide pool, and hence may be used as donors.

The transfer of 5-³H-uridine nucleotides from prelabelled donor cells was tested using as recipients representatives of each functional group, that is, non-communicators (L929), non-selective communicators (calf lens), and selective communicators (HumF) unable to communicate with normal HumE cells. Transfer of nucleotide was quantitated by grain counts from autoradiographs as described in Fig. 1, which summarises the results and presents data obtained previously using HumE cells as donors. The cell line MCF-7 and cells from the primary carcinoma T231 show a complete loss of ability to communicate with any of the recipients tested. Cell line MDA-157 and cells from T162 and T235, however, show a loss of selectivity in communication and donate nucleotide not only to calf lens but also to human mammary fibroblasts. Further experiments (data not shown) with the two established lines confirmed that MCF-7 did not communicate with itself whereas MDA-157 retained this ability.

The main problem in interpreting this data is that HumE¹ cells from primary carcinomas have not been fully characterised as the actual cancer cells. They have, however, been shown to be epithelial in ultrastructure¹², and are the only cells other than human mammary epithelium (HumE), and human mammary fibroblasts (HumF), that have been obtained from primary or secondary breast cancers in this laboratory. HumE¹ cells have never been derived from non-malignant breast tissue or breast secretions, and it is therefore most likely that they do represent the malignant cells of the carcinoma.

This being so, the data presented here show that malignant change may be associated not only with a loss of ability to communicate, but also with a loss of specificity in communication. Other workers have shown that whereas some cancer cells show a reduced ability to communicate directly with other cells^{4,5}, some are good communicators¹⁴. Our results suggest that in both cases a change in the pattern of communication might have occurred. Such changes could be selectively advantageous for the metastasis of cancer cells, enabling them as non-communicators to ignore inhibitory signals from the other epithelial cells, or, as non-selective communicators to receive stimulatory messages from abnormal sources such as fibroblasts.

We thank Dr M. G. P. Stoker for his valuable comments.

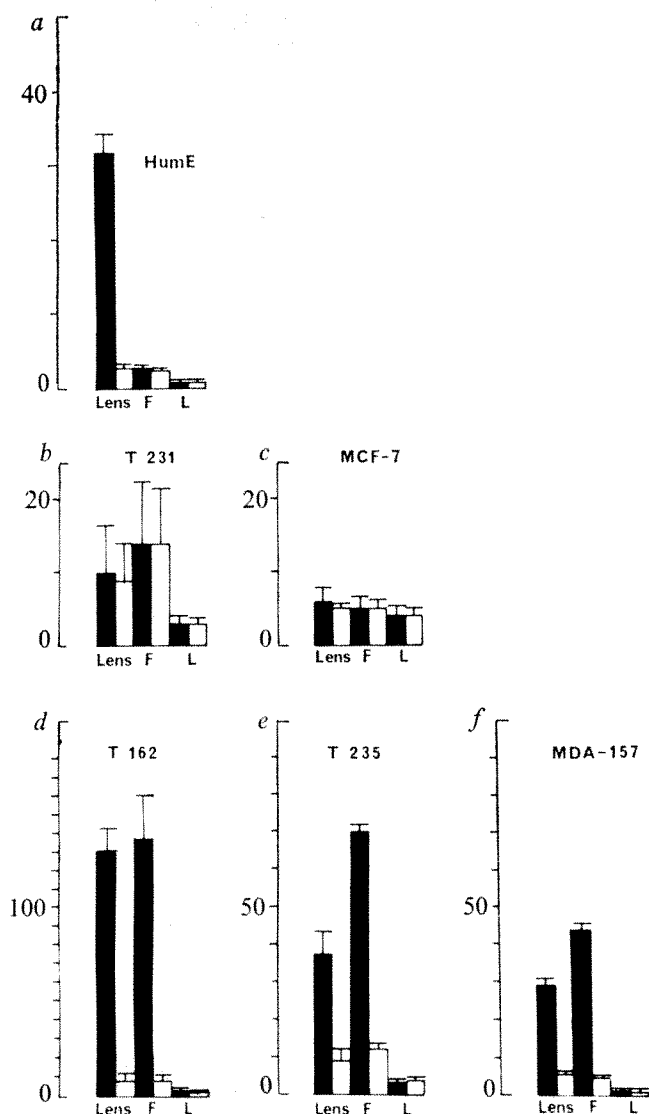

Fig. 1 Grain counts from autoradiographs, showing mean \pm s.e. Closed blocks, recipients touching donors. Open blocks, non-touching recipients. Donor cells were seeded at approximately 6×10^3 cells per 35-mm dish and recipients at 2.5×10^3 per 50-mm dish in the relevant medium (L cells: Dulbecco's modified Eagle's medium with 10% foetal calf serum (FCS); MDA-157 and calf lens: medium 199 with 10% FCS; HumE (ref. 1) and HumF: medium 199 with 20% human serum, 15% FCS, insulin $10 \mu\text{g ml}^{-1}$, hydrocortisone $5 \mu\text{g ml}^{-1}$). After overnight incubation at 37°C , $2 \mu\text{Ci ml}^{-1}$ 5-³H-uridine was added to the donors for 3 h. The cells were then washed three times with medium, and recipient cells, which had just been detached by trypsinisation, were added in medium (199 with 20% human serum, 15% FCS, insulin and hydrocortisone). The donors and recipients were cocultured for 3 h at 37°C , fixed and processed for autoradiography⁸. In each experiment five donor dishes were used and tested with calf lens (twice), HumF (twice) and L cells (once). Experiments were repeated three times and on each dish, grain counts were made over ten recipients touching donors, and over ten recipients touching neither donors, nor other recipients. a, HumE; b, T231; c, MCF-7; d, T162; e, T235; f, MDA-157.

Growing central axons deprived of normal target neurones by neonatal X-ray irradiation still terminate in a precisely laminated fashion

THE development of the central nervous system is characterised by the formation of specific synaptic connections. Highly selective connections form not only between classes of neurones, but also between specific neurones within classes. An additional degree of specificity is observed when the presynaptic axons contact only a limited portion of the target neurone. This kind of specificity is conspicuous in the dentate gyrus (fascia dentata) of the mammalian cerebral cortex. We describe here a situation in which the dentate gyrus offers a unique opportunity to test some of the hypotheses that may explain the selective termination of different afferents on restricted portions of the surface of a neurone.

The most numerous neurones in the dentate gyrus are the granule cells, whose cell bodies are gathered in a dense layer from which the dendrites radiate towards the surface of the brain through the molecular layer (Fig. 1a). The predominant afferent fibre systems that converge on the granule cells are spatially segregated, with little or no overlap, in three distinct zones across the dendritic trees. The outer zone receives fibres from the lateral entorhinal cortex of the temporal lobe, the middle zone is innervated by the medial entorhinal cortex, and the inner zone receives afferents from the hilus fasciae dentatae of both hemispheres¹⁻³ (Fig. 1a).

The majority of granule cells develop postnatally, whereas the sources of their major afferents are generated before birth⁴. Proliferating granule cell precursors are, unlike differentiating or mature neurones, extremely radiosensitive. This allows selective reduction of the granule cell population, while the afferent supplies would be expected to remain intact⁵. The granule cells arise in a temporal sequence from lateral to medial along the curvature of their layer⁴⁻⁶ and irradiation that reduces the number of cells in the lateral limb of the U-shaped granule cell layer totally eliminates the greater part of the medial limb⁵.

We have studied the fate of the axons that normally terminate in a highly selective laminar fashion in the molecular layer of the medial limb of the dentate gyrus when this target is removed by neonatal X-ray irradiation. Rat pups were shielded with lead, except for a field above the hippocampus and the dentate gyrus, and exposed to X rays from a 250-kV source at a distance of 34 cm. At a rate of 400 min⁻¹, 200 R was delivered on postnatal days 2, 3, 5 and 7. A comparable schedule has been shown to irreversibly reduce the number of granule cells to about 20%⁵. The animals were allowed to live for 2-4.5 months when selective lesions were made in the medial or lateral entorhinal cortex or the commissural and association pathways to the dentate gyrus. After a 3-d survival period the animals were killed and histological sections through the brains made and impregnated with silver to show degenerating axon terminals⁷ or treated according to a histochemical method for heavy metals⁸ which in normal brains precisely displays the terminal

Directions: medial—right, anterior—bottom. $\times 50$.

Fig. 2 Section through the dentate gyrus of a normal (top) and a neonatally X-ray irradiated (bottom) rat brain. The sections were stained with a histochemical method for heavy metals⁸ and with thionine, they display in different shades the terminal zones of the afferent pathways also shown in Fig. 1. Arrows point to the hippocampal fissure. $\times 45$.

zones of the three major systems of afferents to the dentate gyrus (Fig. 2).

In the irradiated animals, a histochemically distinct stratification is found not only in the molecular layer above the surviving granule cells but also medially where granule cells are absent (Figs 1, 2). The deep zone in this part is normally delimited by the granule cell layer; however, in the irradiated animals it merges with the stratum oriens beneath the pyramidal cell layer of the Ammon's horn. The degeneration material shows that each histochemically defined zone corresponds to an equally distinct terminal zone of one of the three major systems of afferents to the dentate gyrus. Degeneration in the inner zone is illustrated as an example (Fig. 3). Sections prepared according to the Golgi method, which impregnates single neurones, show that the medially located terminal zones of the entorhinal projections in the absence of granule cells are penetrated by basal dendrites of pyramidal cells of the adjacent Ammon's horn (Fig. 1b). These clearly elongated dendrites normally do not penetrate the terminal zones of the entorhinal fibres (Fig. 1a).

Fig. 3 Section through the dentate gyrus of a neonatally X-ray irradiated rat brain showing terminal degeneration of commissural and association fibres (compare Figs 1, 2). Fink-Heimer silver impregnation. Arrows point to the hippocampal fissure. $\times 45$.

These findings indicate that the laminar distribution of the terminal fields of the pathways converging on the dentate gyrus can exist without the developing axons selectively recognising particular coded portions of the normal target cell surface. This principle is similar to that based on observations made on the laminar distribution of afferents to the piriform cortex and to the dentate gyrus in the reeler mutant mouse. In both locations in the reeler, the termination is relatively independent of the location of the abnormally located target neurones^{9,10,17}.

It has been suggested that the complementary ordering of entorhinal afferents and commissural and ipsilateral association fibres to the molecular layer might be accounted for by a sequential arrival of the two groups of fibres¹¹. The earliest stage examined so far is that of the third postnatal day. At this time, the afferents from the medial and lateral entorhinal cortices and the ipsilateral association fibres have already arrived at the molecular layer and attained the same topographic relationship to each other as they do in mature brains. But, the

commissural projection to the deep zone arrives several days later and terminates in the same field as the ipsilateral association fibres. This illustrates that a sequential arrival of different classes of afferents does not necessarily result in a spatial segregation of their terminal ramification¹².

The abnormal growth of the basal dendrites of pyramidal cells close to the dentate gyrus is probably not a direct effect of radiation, since it has been shown that low-level X-ray irradiation of other parts of the cerebral cortex of immature rats results in dendrites that are shorter than normal¹³. The remarkable extension of the dendrites seen in this study is not understood. It may occur because the dentate gyrus normally hinders further growth and has been removed or, more likely, because the afferents deprived of normal recipients induce the abnormal growth. There are several examples suggesting that dendritic growth is influenced by afferent fibres¹⁴. The preparations described here suggest that neurones may adapt the size of their receptive surface in response to the amount of available afferents. While a reduction in dendritic size, on removal of afferents, has been described^{15,16}, this preparation indicates that the adaptation may also be in the nature of an increase in size.

Corollary discharge to cockroach giant interneurons

A PROBLEM faced by animals as they move about is to distinguish between sensory input which is generated as a direct consequence of the animals' own movements (called refference¹), and that generated by independent external events. One way an animal might handle refference would be to use an approximate copy of motor output (corollary discharge²) to repress or otherwise compensate for it. Cockroaches usually react to gentle puffs of air by rapidly running away, the so-called 'escape response'. Since they do not respond similarly to air currents set up by their own walking (even though the receptors involved are very sensitive to slight air movements from any direction³), they must have some mechanism for recognising and ignoring refferent input. The escape response had originally been thought to be initiated by the activity of the large interneurons known as

giant fibres⁴. This view has been disputed^{5,6}, however, and the function of the giants is at present unclear. I report here evidence that some of these giants are directly excited during walking by neural input which may represent corollary discharge from motor centres in the thorax, and which may aid the insect in handling refferent input.

Neural activity in the ventral nerve cord may be monitored during walking in a cockroach by suspending and eviscerating the insect, and recording with suction electrodes while the animal walks on a lightweight styrofoam ball, rotating this ball beneath itself⁷. In these conditions, several units become active (Fig. 1a). These units, identified as giant fibres on the basis of their large amplitudes and high conduction velocities^{4,7}, are considerably more active during walking (or in response to stimuli such as air puffs), than when the animal is quiet and inactive (Fig. 1b). That the activity of these neurones is not an artefact of the experimental arrangement is suggested by the finding that a similar pattern, that is, activity of giants during walking, near-silence during rest, may also be seen in animals which can move about freely (Fig. 1c, d).

The GFs receive input in the last abdominal ganglion from primary afferents arising at the bases of wind-sensitive hairs on the cerci, a pair of small, peg-like appendages at the end of the abdomen. Since I have observed that all action potentials in the giants during walking travel toward the head, the most obvious explanation for the observed activity is refference through the cerci; that is, excitation of the cercal afferents by air currents set up by the animal's own movements. Removal of the cerci seemed to support this idea, because it caused a marked reduction of neural activity

Fig. 1 Records of neural activity (top traces) in the ventral nerve cord of a single cockroach during walking (a, c) and at rest (b, d). a, b, Giant fibre activity in a suspended animal holding a styrofoam ball. The lower trace shows a monitor of the movement of one rear leg. Downward deflection represents extension. Spontaneous non-giant neural activity present in the nerve cord is hidden in the baseline and not visible in these records due to the low level of amplification used to record from the giant fibres. c, d, Activity in a free-walking animal. The lower trace shows the activity of the main femoral extensor muscle of one leg. Bursts of activity in this muscle indicate that the animal is walking (c). The muscle has a steady, low rate of firing when the cockroach is standing still (d). Note that very much higher levels of firing occur in the ventral cord during walking than at rest.

in the ventral nerve cord during walking. (It does not have any noticeable effect on the walking itself.) I have observed, however, that in intact animals the cercal nerves are never silent, even in a quiet, still room. It seems likely, therefore, that some of this continuous barrage of input from the cerci may provide subthreshold depolarisation to the recipient giant fibres such that any additional input would be enough to fire them. If the background input were removed, the level of depolarisation of the giants caused by other inputs might then be insufficient for the giant fibres to show much activation during walking.

I tested experimentally the hypothesis that there are non-cercal inputs driving the giants. First, I set up an eviscerated, suspended animal with a styrofoam ball as described above⁷. I then arranged a rubber hose over the abdomen of the cockroach so that a continuous stream of air could be blown posteriorly over the cerci. If the giant fibre activity which could be recorded during walking were only, or largely, the consequence of air currents set up by the animal's own movements, then recordings of ventral nerve cord activity during walking in the air stream should show no difference from similar recordings from quiet animals in the air stream. On the other hand, if refference from the cerci due to stimulation by air currents were not the main source of the activity, one would expect to see an increase in activity during walking even in the presence of the air stream. The latter turned out to be the case.

show no difference from similar recordings from quiet cockroach there is an initial burst of activity in the giant fibres in the ventral nerve cord which settles in to fairly high-frequency firing for a minute or more (Fig. 2*a*). If the velocity of the air stream is high enough this activity will soon die away (even though the air is still on) (Fig. 2*b*). In the stream of air, even vigorous puffs of air directed at the cerci from only a few centimetres away elicit no responses from the giant fibres (Fig. 2*c*), suggesting that in this situation the animal cannot generate air currents capable of eliciting any giant fibre response. Nevertheless, when the animal walks, one still observes the strong activity of the GFs also seen in animals not in an air stream (Fig. 2*d*). This activity disappears when the animal is again quiet (Fig. 2*e*).

While these results show that the giant fibre activity observed during walking is not brought about by stimulation of hair receptors by air currents, they do not eliminate the possibility that other receptors on the cerci or elsewhere could be stimulated by walking and thereby excite the giants. Cricket giant fibres, for example, are known to be very responsive to vibrational stimuli⁸. To test the possibility that refference from vibration-sensitive receptors in the posterior of the abdomen was responsible for giant fibre activity during walking, I arranged an animal so that the posterior third of its abdomen was supported by a small platform fastened to a wooden framework resting on the floor. The rest of the animal was supported at the thorax by a holder resting on the bench. By completely severing the abdomen, except for the nerve cord, between the platform and the other holder, it was possible to isolate mechanically the posterior part of the abdomen from the rest of the animal. Tests showed that vibrational stimuli which before the operation easily caused some of the giants to fire failed to do so after the operation. Nevertheless, giant fibre activity concomitant with walking was still apparent. To eliminate the effects of air currents in this situation, I also placed animals treated like this in an air stream, or coated their cerci with petroleum jelly. In no case was the giant fibre activity elicited by walking eliminated.

I conclude from these experiments that refference from cercal or other receptors during walking is not sufficient to account for the giant fibre activity which can be observed. Instead, it seems that the animal actively turns on some of the giants, by sending excitatory signals through small fibres down to the last abdominal ganglion from the thorax or

Fig 2. Records of neural activity in a suspended cockroach in the presence of a continuous, tailward stream of air. Upper traces, ventral nerve cord record; lower traces, leg movement monitor (down is extension). *a*, Onset of the air stream (left) and activity 1 min later (right). *b*, Activity after several minutes. *c*, Activity during delivery of puffs of air (bars above the record) at the cerci. The lack of response to the puffs indicates that in the presence of the air stream, additional air currents are ineffective in eliciting giant fibre activity. *d*, Activity during walking, in the air stream. *e*, Activity during rest, still in the presence of the air stream.

higher centres. It should be possible to test this hypothesis by cutting the ventral nerve cord in the abdomen. Receptors posterior to the lesion would continue to provide their stimulatory input during walking, but the descending excitation would be eliminated, thereby eliminating or drastically reducing giant fibre activity during walking.

This experiment was performed. A cockroach was prepared as before and recordings taken from two positions on the same side of the ventral nerve cord, one just anterior to the last abdominal ganglion, and one at about the middle of the abdomen. After recording the neural activity at both sites during walking (Fig. 3*a*), the entire nerve cord was severed between the two recording electrodes. The effect of this procedure was a dramatic reduction in giant fibre activity recorded at the posterior electrode during walking (Fig. 3*b*). Cutting the nerve cord did not seem to change the responsiveness of the giants to cercal stimulation since gentle puffs of air still elicited vigorous firing in the intact segments of the giants posterior to the cut. The result therefore clearly supports the hypothesis that descending excitation to the giants, which accompanies motor activity in the legs, is the main factor in bringing about the activity during walking.

Compensating for refference can be a special problem for an animal which has sensitive sensory systems which can

Fig. 3 Records of neural activity in a suspended cockroach before (a) and after (b) cutting the ventral nerve cord between the two recording electrodes. Top trace, recording from anterior-most electrode; bottom trace, recording from posterior-most electrode; middle trace, leg movement monitor (down is extension). Note the complete abolition of giant fibre activity in the anterior record (because the headward-moving spikes in the giant fibres cannot pass the cut) and the drastic reduction of activity in the posterior record after the ventral cord was cut.

be stimulated by the animal's own movements and whose activity can trigger evasive behaviour. Some fish and amphibians with lateral line systems handle the problem by suppressing the activity of the sensory systems, either centrally or peripherally^{9,10}. Insects may use this mechanism as well. The activity of some of the giant fibres can be inhibited during walking in the cricket¹¹ and in the cockroach (D. L. Daley, personal communication).

The results I report here show, however, that in cockroaches there is also a population of giants which is excited during walking. Since the excitation seems to derive from thoracic or higher centres and parallels movements of the legs, it can be considered to represent corollary discharge from the thoracic locomotor control centres. Excitation of some of the giant fibres by this corollary discharge presumably would have a role in allowing the animal to respond more quickly to escape-producing stimuli while it is walking, but at present even this possibility is only speculation, and the mechanism by which it would function is completely unknown.

D. L. Daley and B. J. Mendius made useful comments on the manuscript. The work was supported by a Bio-Medical Science Support Grant and USNIH grant NS12142.

Regulation of adenylate cyclase activity in glial–adrenal hybrid cells

SOMATIC cell hybrids, formed by fusion of hormone-responsive and insensitive cells, have been used to evaluate the structure and genetic regulation of the hormone-sensitive adenylate cyclase system^{1–6}. In the cell hybrids studied so far, catecholamine-sensitive adenylate cyclase activity was lost when catecholamine-responsive and insensitive cells were fused. Prostaglandin E₁

(PGE₁)-sensitive adenylate cyclase activity, on the other hand, was retained in hybrids between PGE₁-sensitive and insensitive cells. Where examined, the presence or the absence of hormone sensitivity in the hybrids closely correlated with hormone receptor activity as measured by ligand-binding assays^{1–3}. These observations suggest that genetic mechanisms may control the expression of hormone responsiveness at the level of the hormone receptor. To examine these patterns of regulation further, we have formed cell hybrids between rat glial tumour cells with adenylate cyclase activity responsive to β -adrenoceptor agonists⁷ and mouse adrenocortical tumour cells with adrenocorticotrophic hormone (ACTH)-sensitive adenylate cyclase activity⁸. Besides having distinct functional hormone receptors, the adenylate cyclases of parental cells exhibit marked quantitative differences in response to fluoride ion^{7,8}. We find that the glial–adrenal hybrids retain the adrenaline-sensitive adenylate cyclase activity characteristic of the glial parent, and lose ACTH sensitivity. The level of the fluoride response, however, is characteristic of the adrenal parent. These data indicate that hormone receptor and catalytic unit activities in the adenylate cyclase system are independently regulated.

The clones used in the cell hybridisation experiments presented here are listed and described in Table 1. C6 cells were from a rat glial tumour cell line¹⁰; Y1 and OS3 adrenocortical cells were from mouse adrenocortical tumour cell lines^{11,12}. The isolation and characterisation of C6 cells deficient in thymidine kinase activity (TK[−]) has been described previously¹³. The isolation of Y1, OS3 and C6 clones deficient in hypoxanthine–guanosine phosphoribosyl transferase activity (HGPRT[−]) was accomplished by mutagenesis with ethyl methanesulphonate 300 μ g ml^{−1} and selection with 6-thioguanine 5 μ g ml^{−1}. The HGPRT[−] parents had less than 5% of the HGPRT activity¹⁴ of controls and did not form colonies when 10⁷ cells were plated in the presence of amethopterin¹⁵. Cell hybrids were prepared by fusing 10⁶ HGPRT[−] adrenal cells in monolayers with 10⁴ TK[−] glial cells, using chemically inactivated Sendai virus (Connaught Laboratories) as described by Watkins¹⁶. After fusion, hybrids were selectively grown in medium containing hypoxanthine, thymidine and amethopterin^{13,17}. The hybrid nature of the cells isolated in selective growth conditions was confirmed by analysis of karyotypes¹⁸. Cells isolated after fusing Y1_{HGPRT[−]} or OS3_{HGPRT[−]} cells with C6_{TK[−]} cells were polyploid with slightly fewer than 14 metacentric chromosomes denoting the contribution from one glial and one adrenal parent (Table 1).

The adenylate cyclase systems from glial and adrenal parental cells were readily distinguished by their responses to hormones and to fluoride. In the C6 cell lines, adenylate cyclase activity was increased by adrenaline, whereas in the Y1 cell line, the enzyme was stimulated by ACTH (Table 1). High levels of fluoride-stimulated enzyme activity (approximately 200 pmol cyclic AMP formed per min per mg protein) seemed to be a characteristic feature of the mouse adrenocortical tumour cells^{8,9,19}, and also was observed in the OS3 adrenal line, an ACTH-insensitive, Y1 cell variant (for example, Table 1). These levels of fluoride-stimulated adenylate cyclase activity were \geq threefold those seen in C6 cells (ref. 7), in TK[−] and HGPRT[−] subclones (Table 1), or in C6_{TK[−]} \times C6_{HGPRT[−]} hybrids (Table 1).

Hormone sensitivity in C6_{TK[−]} \times Y1_{HGPRT[−]} hybrids resembled that of the C6_{TK[−]} glial cell parent. Adenylate cyclase activity was stimulated by adrenaline, but not by ACTH (Table 1). In the presence of fluoride, adenylate cyclase activity was \geq 200 pmol cyclic AMP formed per min per mg protein, characteristic of the Y1_{HGPRT[−]} adrenal parent (Table 1). These patterns of expression were observed consistently in 11 different C6_{TK[−]} \times Y1_{HGPRT[−]} hybrid populations, in four C6_{TK[−]} \times OS3_{HGPRT[−]} hybrids, and also in clonal isolates from each (Table 1).

The retention of adrenaline sensitivity (β^+) and loss of ACTH sensitivity (ACTH[−]) in the adenylate cyclase system of glial (β^+ , ACTH[−])–adrenal (ACTH^{+, β^-) hybrids, suggest the presence of regulatory influences distinct from those reported previously^{1–4}. The high level of fluoride-stimulated adenylate cyclase activity observed in the glial–adrenal hybrids but not in glial–glial hybrids (Table 1) indicate the contributions of adrenal components}

Table 1 Properties of parental clones and hybrids

	Cell line	Chromosome number		Adenylate cyclase activity				n
		Total	Metacentric	Basal	Adrenaline	ACTH	NaF	
Parents	C6 _{TK} ⁻	35	14	7 ± 2	94 ± 1	ND	66 ± 6	4
	C6 _{HGPRT} ⁻	42	14	10 ± 1	81 ± 5	ND	61 ± 7	4
	Y1 _{HGPRT} ⁻	40	0	6 ± 1	ND	40 ± 3	217 ± 23	5
	OS3 _{HGPRT} ⁻	42	0	2	2	2	190	1
Hybrids								
	C6 _{TK} ⁻ × Y1 _{HGPRT} ⁻	78 (72-89)	12	13 ± 3	66 ± 16	14 ± 3	263 ± 31	11
	C6 _{TK} ⁻ cloned	83	ND	26	199	24	424	1
	C6 _{TK} ⁻ × OS3 _{HGPRT} ⁻	82 (73-88)	11	5 ± 3	60 ± 8	4 ± 2	231 ± 55	4
	C6 _{TK} ⁻ cloned	88 (79-95)	9	6	79	6	437	1
	C6 _{TK} ⁻ × C6 _{HGPRT} ⁻	72	ND	6 ± 1	43 ± 8	6 ± 1	59 ± 7	5

Chromosome numbers for parental lines are modal numbers based on scores from at least 50 spreads. Values for hybrids are either modal numbers or averages with the range given in parenthesis.

Adenylate cyclase activity is given as pmol cyclic AMP formed per min per mg protein ± s.e.m. The number of determinations is given under *n*. Adrenaline 33×10^{-5} M; ACTH $1-24 \times 10^{-5}$ M; and NaF 15×10^{-3} M were added where indicated. C6 cells are insensitive to ACTH and Y1 cells are insensitive to adrenaline^{7,9}. Activity was assayed in cell homogenates by conversion of labelled ATP to labelled cyclic AMP^{7,8}.

ND, Not determined.

The total hybrid population surviving each selection was analysed. Data were accumulated from the *n* hybrid preparations indicated in the last column.

determining the catalytic activity of the adenylate cyclase system. Glial components of the fluoride response may be present but masked. Membrane fusion experiments of Orly and Schramm²⁰ suggest that a receptor from one cell should be able to couple functionally with the adenylate cyclase from another cell. These observations raise the interesting possibility that the adenylate cyclase system in the glial-adrenal hybrids is a mixture of components from each parent.

We thank Drs J. Logothetopoulos and C. J. Ingles for discussions, Mrs Deborah Brymer for assistance and Dr W. Rittel (Ciba-Geigy) and Dr H. Strade (Organon) for gifts of ACTH₁₋₂₄. This work was supported by the MRC of Canada.

tricyclic antidepressant drugs may also have this activity. To test this hypothesis, four tricyclic antidepressants—representing four different structural types—were tested on the H₂ receptor linked to adenylate cyclase in homogenates of the guinea pig hippocampus and cortex. Both dimaprit and histamine were used as agonists. Dimaprit has potent activity at the H₂ receptor with negligible activity at the H₁ receptor, that is, less than 0.0001% of that of histamine².

Each experiment was done on fresh preparations of hippocampus and cortex from adult guinea pigs. The tissues were homogenised in a Potter-Elvehjem glass-Teflon vessel in 50 volumes of a medium containing 0.32 M sucrose, 5 mM Tris-chloride, 1 mM EGTA, and 1 mM dithiothreitol, pH 7.4. The method for measuring adenylate cyclase activity has been described³. The assay system contained 75 mM Tris-chloride (pH 7.4), 1 mM ATP, 2 mM MgCl₂, 1 mM cyclic AMP, 5 mM phosphocreatine, 0.5 mg ml⁻¹ creatine kinase (ATP creatine phosphotransferase, EC 2.7.3.2) 4 mM theophylline, 10⁻⁵ M GTP, 0.1 M sucrose, 0.3 mM EGTA, 0.3 mM dithiothreitol, and enzyme protein (150-190 μg) in a final volume of 225 μl. All assays were performed in triplicate. All additions were made to the assay tubes on ice. They were then transferred to a 30 °C shaking incubator and preincubated for 5 min to allow the enzymatic activity to reach a steady rate and to eliminate the influence of any lag periods in hormone activation. After the preincubation period, 25 μl α-³²P-ATP (1-2 Ci) were added and the reaction was allowed to proceed for 13 min when it was stopped by adding 100 μl of 1% sodium dodecylsulphate. After addition of 650 μl of ³H-cyclic AMP (5,000-10,000 c.m.p.) to monitor recovery, the labelled cyclic AMP was isolated with alumina and Dowex AG-50W (ref. 4). The reaction was linear with protein concentration⁵ in the range used and for at least 15 min after the addition of the α-³²P-ATP. Curve fitting techniques⁶ with the PROPHET (ref. 7) computer system were used to estimate the apparent ED₅₀ (50% effective dose) values, maximum stimulation by agonists, and parallelism of the dose-response curves. Antagonism was analysed by means of Schild plots^{8,9}.

All four tricyclic antidepressants shifted the dose-response curve of histamine- and dimaprit-stimulated adenylate cyclase in a parallel manner. Figure 1 shows histamine-stimulated adenylate cyclase activity in the absence and presence of amitriptyline. The competitive nature of antagonism by amitriptyline and imipramine was further revealed by Schild plots. As shown for amitriptyline (Fig. 2) the slope of the Schild plot, with either histamine or dimaprit as agonist, is 1.02, which is not significantly

Tricyclic antidepressant drugs block histamine H₂ receptor in brain

THE observation that cyproheptadine is a competitive antagonist of the histamine H₂ receptor linked to adenylate cyclase in brain¹ suggested that the chemically similar

Fig. 1 Increase in adenylate cyclase activity of the guinea pig hippocampus in response to varying concentrations of histamine in the absence and presence of different concentrations of amitriptyline. Each point is the mean of triplicate determinations on a single enzyme preparation. Amitriptyline alone did not affect basal activity. Control, Δ ; amitriptyline at 4×10^{-7} M, \square ; 10^{-6} M, \circ ; 4×10^{-6} M, \bullet ; and 10^{-5} M, \blacksquare .

different from unity. Table 1 summarises the pA_2 values of the four antidepressants. Amitriptyline is the most active drug, about as potent as cyproheptadine ($pA_2=7.43$, ref. 1). Dibenzepin and iprindole have about 100-fold less affinity for the cyclase. As the histamine-sensitive adenylate cyclase in broken cell preparations of guinea pig cortex and hippocampus respond identically to histamine, dimaprit and antagonists¹, it was appropriate to compare the sensitivities

Table 1 pA_2 values of tricyclic antidepressant drugs in inhibiting histamine- and dimaprit-stimulated adenylate cyclase activity in homogenates of guinea pig hippocampus

Drug	Histamine pA_2 values	Dimaprit
Amitriptyline	7.23 ± 0.27 (7)	7.47 ± 0.55 (7)
Imipramine	6.39 ± 0.16 (7)	6.61 ± 0.19 (6)
Dibenzepin	5.49 ± 0.11 (3)	5.81 ± 0.11 (3)
Iprindole	5.63 ± 0.11 (3)	5.49 ± 0.27 (3)

Values are means \pm s.d. The numbers of different hippocampi that the drugs were tested on are given in parentheses.

of the cyclases in the cortex and hippocampus to tricyclic antidepressants. Figure 2 shows that the values obtained on homogenates from cortex are described by the same Schild plot as derived from observations on homogenates of the hippocampus.

It should be noted that these drugs also blocked dimaprit-activated adenylate cyclase activity in a competitive manner. Since dimaprit has negligible H_1 -antagonist activity² the inhibition of dimaprit-sensitive adenylate cyclase by tricyclic antidepressants permits their classification as histamine H_2 antagonists. The pA_2 values of H_2 antagonists on histamine- or dimaprit-activated adenylate cyclase activity in homogenates of guinea pig hippocampus^{1,10}, and cortex¹, and cardiac ventricles³ were very nearly identical to the pA_2 values on pharmacological preparations thus showing that blockade of this adenylate cyclase in these tissues reflect pharmacological effects on the H_2 receptor in other tissues.

Brain concentration of imipramine after a single dose of 15 mg per kg body weight intramuscularly was found¹¹ in

Fig. 2 Schild plot for inhibition by amitriptyline of dimaprit- and histamine-stimulated adenylate cyclase activity in the guinea pig hippocampus and cortex. The dose ratios (DR) were calculated as the ratio of the ED_{50} of histamine in the presence and absence of different concentrations of amitriptyline (B). Simple competitive antagonism results in a straight line of slope 1 when $\log(DR-1)$ is plotted against $\log B$; and the intercept with the abscissa is $-\log K_B$, where K_B is the apparent dissociation constant for the antagonist-receptor interaction; $-\log K_B$ is referred to as pA_2 . The slope of the line is 1.02, not significantly different from unity, and the pA_2 value is 7.35. Each point is the mean of experiments on tissue from at least two animals. Dimaprit stimulated activity in \bullet , hippocampus and \square , cortex. \circ , Histamine stimulated activity in hippocampus.

Table 2 Potencies of some tricyclic antidepressant drugs in blockade of the histamine H_2 receptor, the muscarinic receptor, and in inhibiting uptake of 5-hydroxytryptamine (5-HT) and noradrenaline (NA)

Drug	Anti- H_2 activity		Antimuscarinic activity		IC ₅₀ (M) for inhibition of uptake:	
	$K_B^*(M)$	IC ₅₀ [†] (M)	$K_B^{\ddagger}(M)$	$K_B^{\S}(M)$	5-HT (ref. 14)	NA (ref. 15)
Amitriptyline	3.4×10^{-8}	6.8×10^{-8}	3.3×10^{-8}	8.3×10^{-9}	4.9×10^{-7}	5.5×10^{-8}
Imipramine	2.4×10^{-7}	4.8×10^{-7}	2.0×10^{-7}	6.5×10^{-8}	2.8×10^{-7}	1.0×10^{-6}
Dibenzepin	1.5×10^{-6}	3.0×10^{-6}	1.8×10^{-6}	—	—	—
Iprindole	3.2×10^{-6}	6.4×10^{-6}	—	—	1.0×10^{-6}	—

*Dimaprit as agonist, from Table 1.

[†]Calculated according to: $IC_{50} = K_B(1 + [A]/K_A)$, where K_B = the apparent dissociation constant for the drug-receptor interaction; $[A]$, agonist concentration, taken arbitrarily as $[A] = 2 \times K_A$; and K_A is the apparent dissociation constant for the dimaprit-receptor interaction which equals the ED_{50} value.

[‡]From ref. 12, where 3H -N-methyl-4-piperidylbenzilate was used as the labelled ligand ($K_B = 5 \times 10^{-10}$ M), at a concentration of 5×10^{-10} M.

[§]Calculated from ref. 13, where 3H -3-quinuclidinylbenzilate was used as the labelled ligand ($K_B = 3 \times 10^{-10}$ M), at a concentration of 6×10^{-11} M.

rat to be $1,500\mu\text{g l}^{-1}$, which corresponds to $5.4 \times 10^{-6}\text{ M}$. This concentration is higher than the apparent K_B value (Table 2), suggesting that the brain H_2 receptors could be occupied *in vivo* after administration of pharmacologically active doses. Among the mechanisms proposed to account for the pharmacological effects of the tricyclic antidepressants are blockade of re-uptake of noradrenaline and of 5-hydroxytryptamine and blockade of muscarinic receptors. Table 2 shows the potency of these drugs at these sites and at the H_2 receptor. Their K_B values at the H_2 receptor and muscarinic receptor (column 3 of Table 2) are surprisingly similar. The IC_{50} values (concentrations for 50% inhibition) for uptake cannot be directly compared with the IC_{50} values for blocking the H_2 receptor because the affinities of 5-hydroxytryptamine and noradrenaline for the uptake system are not known; but the estimates (Table 2) suggest that potency for H_2 blockade is at least comparable with potency in blocking uptake of the amines.

Nevertheless, the information available cannot support an assertion that blockade of the H_2 receptor (or any other single action of these drugs) contributes to their therapeutic effect. But some of the pharmacological effects of the antidepressant drugs may rest on blockade of H_2 receptors. For example, histamine increases fluid consumption in rats by a central mechanism¹⁶⁻¹⁸, and tricyclic antidepressant drugs diminish fluid consumption in rats¹⁹. One of the rare adverse effects of these drugs is hallucinations²⁰; perhaps pertinent is the finding that the hallucinogen, *d*-lysergic acid diethylamide, also blocks the H_2 receptor¹. Of special and practical interest is that amitriptyline has greater affinity for the H_2 receptor (Table 1) than does cimetidine ($pA_2=6.22$; ref. 1), the H_2 antagonist that is so effective in treating peptic ulcer^{21,22}. The antimuscarinic activity of some of the tricyclic antidepressants should further enhance their usefulness in treating this disease. Like cimetidine, antidepressant drugs have been shown to decrease gastric acidity in man²³ and gastric acid secretion in laboratory animals²⁴⁻²⁷ and to prevent gastric ulcer formation in animals^{24,27-30}—effects that were also noted with an antidepressant drug lacking antimuscarinic activity²⁷.

Reversal of the Na-K pump and apparent affinity for intracellular potassium

CENTRAL to all formulations of the transport mechanism of the membrane Na-K pump should be the description of cation binding and release. The acceptance sites for transport by the pump, external sites for K and internal sites for Na, have been extensively studied, and linked to the activating sites of the associated Na,K-ATPase¹. By contrast, little is known about the discharge sites of the pump, although proposed characteristics of these sites have vital roles in various transport and enzyme schemes, such as cyclical conversions of discharge sites for one cation into acceptance sites for the other. We have studied the apparent affinity for K at its intracellular discharge sites by measuring the rate of ATP synthesis as a function of the internal K concentration in resealed red blood cell ghosts, where the Na-K pump is driven in reverse by the downhill efflux of K and influx of Na: the observed $K_{0.5}$ for internal K was 0.3 M.

Resealed ghosts were prepared from fresh, human red blood cells, following the procedure of Bodemann and Passow² and Bodemann and Hoffman³. Cells, washed three times in 160 mM choline chloride-10 mM Tris-HCl (pH 7.4), were suspended at 50% haematocrit in isotonic Tris-HCl (166 mM, pH 7.4) at 0 °C, and then rapidly mixed with 10 volumes of ice-cold haemolysing solution⁴ containing 1 mM ATP, 2 mM ADP, 9 mM MgCl_2 , 10 mM iodoacetate, and 5 mM ^{32}P -phosphate. After 5 min the salt concentration was restored to 160 mM by adding 3.2 M KCl (or KCl plus choline chloride at a total concentration of 3.2 M), to give final KCl concentrations of 60-160 mM. After a further 5 min the ghosts were resealed by incubating for 60 min at 37 °C. The ghosts were then washed five times in 160 mM choline chloride-10 mM Tris-HCl. Most ghost cells prepared in this manner are relatively impermeable to cations⁵ and capable of active transport⁶ of Na and K.

To measure incorporation of ^{32}P -phosphate into ATP, the resealed ghosts, at a final haematocrit of 3%-5%, were incubated at 37 °C in 160 mM NaCl-10 mM Tris-HCl (pH 7.4) in the presence and absence of 0.2 mM ouabain. At timed intervals samples were removed and the ghosts washed twice at 4 °C in 160 mM choline chloride-10 mM Tris-HCl. The packed ghosts were haemolysed in a solution containing 1.4 mM ATP and 2 μM phosphate. (To estimate the initial level of internal K and ^{32}P -phosphate, ghosts that were resealed but not incubated were treated the same way.) Aliquots were then removed to determine the K and haemoglobin contents. To precipitate the protein in the haemolysate ice-cold trichloroacetic acid was added (final concentration 5%), and the mixture centrifuged.

Table 1 Incorporation of ^{32}P -orthophosphate into organophosphate by reversal of the Na-K pump in resealed red cell ghosts

Expt	% Of total initial radioactivity in organophosphate		
	Total	Plus ouabain	Ouabain-sensitive
1	2.19	1.73	0.46
2	3.41	2.97	0.44
3	2.05	1.91	0.14
4	2.73	2.17	0.56
5	3.51	3.15	0.36

Ghosts were resealed in a solution containing 160 mM KCl, plus other constituents as given in the text. The ghosts were then incubated for 15 min at 37 °C in 160 mM NaCl-10 mM Tris-HCl, in the presence and absence of 0.2 mM ouabain. The ouabain-sensitive incorporation of ^{32}P into organophosphate is assumed to represent synthesis of ATP by reversal of the Na-K pump.

Fig. 1 Time course of incorporation of ^{32}P -orthophosphate into organophosphate by reversal of the Na-K pump. Red cell ghosts were resealed in solutions containing KCl at 160 mM (●) or 80 mM (○), plus other constituents as given in the text. At the times indicated during incubation, samples of the ghosts were taken for determination of ^{32}P -labelled organophosphate and of K concentration. In each experiment, the ouabain-sensitive incorporation of ^{32}P into organophosphate (as a fraction of the initial content of ^{32}P -orthophosphate) was normalised to the value at 15 min for ghosts resealed in 160 mM KCl. Results shown are from four experiments with ghosts resealed in 160 mM KCl (mean final [K] in the ghosts, $95 \text{ mM} \pm 8$, s.e.m.). In three of these experiments ghosts resealed in 80 mM KCl were also used (mean final [K], $54 \text{ mM} \pm 6$). Vertical bars indicate s.e.m. values (except for the value to which the others were normalised). The lines were fitted by eye.

The supernatant material was adjusted to pH 5–6 with Tris, unlabelled phosphate added as carrier, and inorganic phosphate extracted as the phosphomolybdate complex⁴. Radioactivity remaining after the extractions, ' ^{32}P -organophosphate', was then measured by liquid scintillation counting.

In these conditions ghosts resealed in 160 mM KCl and incubated for 15 min in 160 mM NaCl incorporated about 3% of the initial ^{32}P -phosphate into the organophosphate fraction (Table 1). Of this incorporation, about 14% was inhibited by ouabain (0.4% of the initial ^{32}P -phosphate), and this synthesis is assumed to reflect reversal of the Na-K pump^{1,5}. In similar experiments Garrahan and Glynn⁴ found 0.5% of the initial ^{32}P incorporated after 15 min, and 40% of this was ouabain-sensitive (0.2% of the initial ^{32}P).

In a preliminary experiment the extract was separated by ion-exchange chromatography⁴. ouabain-sensitive incorporation into material eluting with authentic ATP was demonstrated, together with a smaller fraction eluting with ADP. Garrahan and Glynn⁴ similarly found that the bulk of incorporated ^{32}P eluted with ATP; the labelling of ADP was attributed to the action of adenylate kinase. In the same experiment ouabain-sensitive influx of ^{22}Na was also demonstrated⁶. This flux could not result from Na-Na exchange since the ghosts, containing a high K content, were virtually free of internal Na.

The time course of ouabain-sensitive incorporation of ^{32}P into organophosphate was nearly linear for 20–30 min, with ghosts resealed in either high or low KCl media

(Fig. 1), although there was considerable error in the estimation of incorporation at 30 min. In these and subsequent experiments the rate of incorporation in each case is normalised to that of ghosts resealed in 160 mM KCl and incubated for 15 min, measured concurrently, defined as 1.0. Normalisation was necessary because of the variation in absolute incorporation between different preparations of ghosts (Table 1). The measured K concentrations were less than those of the resealing media (Fig. 1), but the loss did not occur during the experimental incubation: there was no detectable decrease in K content between 0 and 30 min.

Since it was possible to estimate in 15 min the initial rate of ouabain-sensitive incorporation, the effect of the internal K concentration on this rate was examined (Fig. 2). Although there were again large errors associated with the estimates of incorporation, there was a positive correlation between the measured K concentration within the ghosts and the rate of synthesis. Moreover, these data, replotted in double-reciprocal form (Fig. 2, inset) fit well a linear relationship, giving a $K_{0.5}$ of 0.3 M for K-activation of ATP synthesis through reversal of the Na-K pump.

This $K_{0.5}$ is two to three orders of magnitude greater than the apparent affinity for K at sites inhibiting the binding of ATP^{7,8}, sites that have been interpreted⁹ as representing the internal discharge sites for K. By contrast, this $K_{0.5}$ for pump reversal is only twofold greater than the K_i for K as

Fig. 2 Incorporation of ^{32}P -orthophosphate into organophosphate in resealed ghosts containing various K concentrations. Ghosts were incubated for 45 min at 37 °C. The horizontal and vertical bars indicate s.e.m. values for, respectively, the measured K concentrations in the ghosts and the ouabain-sensitive incorporation of ^{32}P into organophosphate (except for the values at the highest K concentration, to which the others were normalised). The results shown are from four experiments, each with ghosts containing four different K concentrations, plus a fifth experiment with ghosts at two K concentrations. In the inset, these data are replotted in double reciprocal form, and the straight line was fitted by the method of least squares; the calculated $K_{0.5}$ is 297 mM.

a non-competitive inhibitor of K-dependent phosphatase activity of the Na,K-ATPase¹⁰, an effect considered¹⁰ as product-inhibition through occupancy of discharge sites for K.

For K-K exchange through the pump the concentration of internal K for half-maximal activation is only 10 mM (ref. 11), well below the $K_{0.5}$ found here. This discrepancy may reflect mechanistic differences between the two processes; for example, K influx occurs with K-K exchange but not with pump reversal, so if influx becomes rate-limiting before internal K sites (involved in both exchange and reversal) are saturated, then different responses to internal K might be seen. Alternatively, K-K exchange may involve cyclical changes in K sites, rather than a simple shuttling through K channels. Since the K_i for K as a competitor to Na at the internal Na sites is 9 mM (ref. 12), close to the $K_{0.5}$ for K in K-K exchange, it is tempting to consider that efflux during K-K exchange involves those Na sites. Further quantitation of Na-K interactions¹¹ as well as elucidation of the role of inorganic phosphate¹³ will be needed before the nature of the exchange mechanism can be fully resolved.

For the Na-K pump the data can be accommodated in formulations featuring K discharge sites ($K_{0.5}$ approximately 300 mM) that may be cyclically converted to acceptance sites for Na (K_i for K about 9 mM), the latter possibly also serving in K-K exchange as acceptance sites for K ($K_{0.5}$ approximately 10 mM). In any case, our results clearly demonstrate the presence of internal low-affinity sites for K in conditions in which Na acceptance sites would be expected (that is, high nucleotide content and physiological K concentration). The observations thus support formulations¹⁴⁻¹⁶ in which distinct sites and channels for Na and K co-exist, perhaps on different subunits, perhaps with interconversion of these two classes of channels with each pump cycle.

Analgesic activity of lipotropin C fragment depends on carboxyl terminal tetrapeptide

A SERIES of peptides with morphine-like activity has been identified in extracts of pituitary¹⁻³ and brain⁴⁻⁷. With the exception of Leu-enkephalin, all those characterised represent some fraction of the 31-residue C fragment—a specific activation product of lipotropin^{1,8}. Several attempts have been made to define the receptor requirements of opiate peptides^{9,10} and to make potent and stable agonists^{5,11,12}, but essentially all the studies have been based on the easily synthesised NH₂-terminal pentapeptide of C fragment, Met-enkephalin. Unlike the enkephalins, C fragment has a high potency in its central actions¹³⁻¹⁶, *in vivo* and *in vitro*, and it is relatively stable to brain peptidases¹⁷⁻¹⁹. C fragment is the only naturally occurring peptide to possess strong analgesic properties and have a long lasting action²⁰. It is clear that specific regions of the molecular structure, not present in γ and α endorphin or Met-enkephalin, have a role in the expression of its central activity. We present here evidence that the COOH-terminal tetrapeptide of C fragment, Lys-Lys-Gly-Gln, is responsible for the unique affinity of C fragment for brain opiate receptors and that the presence of all four residues is essential for the high analgesic potency.

Lipotropin, C fragment (61-91) and C' fragment (61-87) were isolated from porcine pituitary¹. The 61-89 peptide and the ϵ -N-pentacitraconyl derivative of C fragment were prepared as described in Table 1. Opiate binding assays were carried out by measuring the ability of peptides to reduce the specific binding of ³H-naloxone and ³H-dihydromorphine to opiate receptors in washed synaptosomal membranes from rat brain. Analgesic potencies were determined by a tail flick assay using rats with indwelling cannulae²¹.

The affinity of C fragment (lipotropin 61-91) for brain opiate receptors, assessed by displacement of ³H-naloxone, was decreased by removal of the COOH-terminal glutamine and glycine residues (Table 1). C' fragment (61-87), which lacks two lysine residues in addition to glutamine and glycine, exhibited a much lower affinity; its ability to displace ³H-naloxone was 40 times less than that of C fragment.

Table 1 Binding of C fragment and derivatives to brain synaptosomal membranes

Peptide	Concentration required to displace 50% of bound opiate	
	³ H-naloxone (10 ⁹ M)	³ H-dihydromorphine (10 ⁹ M)
C fragment	2.6	2.2
C fragment (61-89)	7 ± 2 (4)	2.2 ± 0.5 (4)
C' fragment (61-87)	100	42
[CT ₅] C fragment	4,000	710
Acid-treated [CT ₅] C fragment	3.0	2.5

Desglutamine desglycine C fragment (61-89) was obtained by prolonged carboxypeptidase A digestion of citraconylated C fragment. The product was isolated by gel filtration on Sephadex G50 in 200 mM N-ethylmorpholine acetate at pH 8.5. ϵ -N-pentacitraconyl C fragment ([CT₅] C fragment) was prepared by trypsin digestion of citraconylated porcine lipotropin. The peptide was purified by gel filtration on Sephadex G50 in 20 mM Tris-HCl at pH 8.5 and by ion-exchange chromatography on DEAE-Sephadex A25 at pH 8.5. Citraconyl groups were removed from peptides by incubation with 100 mM pyridine acetate at pH 4.0 for 24 h at 37 °C. Volatile buffers were removed by evaporation in a vacuum and by desalting on Sephadex G25. Peptide purity was established by amino acid analysis and NH₂- and COOH-terminal determinations. Opiate binding assays were performed using displacement of radiolabelled alkaloids from brain synaptosomal membrane preparations as a measure of the relative affinity of a given peptide⁹. The percentage error of the mean of a determination was generally better than 3%. The standard deviations shown include results obtained from two preparations of the 61-89 peptide.

Similar results were obtained when displacement of ^3H -dihydromorphine was used as an index of receptor binding, but the decrease in affinity associated with removal of the COOH-terminal residues from C fragment was less marked. Thus, desglutamine desglycine C fragment (61–89) exhibited a receptor affinity comparable to C fragment and removal of the two lysine residues reduced affinity 19-fold.

The results indicate an important role for the paired lysine residues, and to a lesser extent glycine and glutamine at the COOH-terminus, for the binding of C fragment to brain opiate receptors. A requirement for positive charges on the lysine residues was suggested by study of the binding properties of a pentacitraconyl derivative of C fragment, in which the five lysine amino groups were masked by anionic substitution. The affinity of the citraconyl derivative, measured by displacement of naloxone, was three orders of magnitude less than the affinity of C fragment.

It was notable that the potency of ϵ -N-pentacitraconyl C fragment in displacing ^3H -dihydromorphine was greater than its potency in displacing ^3H -naloxone (Table 1) and in this respect the citraconylated derivative resembles Met-enkephalin. This is consistent with the finding that modifications in the COOH-terminal region of C fragment have more effect on the inhibition of naloxone binding than on the inhibition of morphine binding.

The analgesic activities exhibited by C fragment, the 61–89 peptide and C' fragment reflected their abilities to displace ^3H -naloxone in the binding assay. Removal of the glutamine and glycine residues from the COOH-terminus of C fragment reduced the analgesic potency (Fig. 1). The effect of removing the two lysine residues, shown in the properties of C' fragment, was to cause a severe loss of potency; the 61–87 peptide possessed approximately 1/500th the activity of C fragment.

Although the potency of C' fragment was low, its analgesic action persisted for several hours. In contrast, the weak analgesic action of Met-enkephalin is transient^{22,23}. It is clear that the duration of analgesia, and not the potency, is related to *in vivo* stability. Met-enkephalin, for example, undergoes rapid degradation in the presence of brain homogenates²⁴ whereas C fragment and C' fragment are comparatively stable¹⁷. The long peptides seem to possess preferred conformations which protect the NH₂-terminal region from enzymatic attack²⁵. In particular it is notable that C' fragment resembles C fragment in having a high stability to

attack by aminopeptidases, which would indicate that the two peptides possess similar conformations in solution. Our results suggest that the four residues at the COOH-terminus of C fragment contribute to receptor affinity by participating in a specific interaction within the peptide-receptor complex and not by stabilising an intrinsic conformation of the peptide molecule.

The COOH-terminal residues of C fragment, Lys-Lys-Gly-Gln, are highly resistant to the action of carboxypeptidases in brain¹⁸. Furthermore, loss of all four residues leads to a large reduction in analgesic potency and removal of additional residues has little further effect on binding affinity⁹ or analgesia²⁰. Thus, the COOH-terminal region of C fragment fulfils a dual function: it confers stability on the peptide against proteolysis and it provides a structure important for receptor affinity.

Fig. 1 Log dose-response curves for analgesia produced by intraventricular injection of peptides in the rat. a, C fragment 61–91; b, 61–89 peptide; c, C' fragment (61–87). Peptides were dissolved in 0.9% saline and injected in a volume of 5 μl through indwelling lateral ventricular cannulae. Tail-flick latencies were measured before and at intervals up to 3 h subsequent to administration of the peptides. The ordinate values give the tail-flick latency at 30 min after injection. There were no significant differences between groups in baseline latency (2–4 s).

Proinsulin conversion to desalanyl insulin by α_2 -macroglobulin-bound trypsin

HARPEL and Mosesson¹ observed that α_2 -macroglobulin-bound trypsin hydrolysed low molecular weight ester and amide substrates at rates comparable with those of free protease, but degradation of high molecular weight proteins was markedly inhibited. To account for this finding, Barrett and Starkey² introduced the novel concept of steric entrapment of endopeptidases by α_2 -macroglobulin. Neurath and Walsh³ have recently reviewed the role of proteolytic enzymes in the conversion of a variety of enzymes, hormones, and other physiologically active proteins from inactive precursors to active forms by limited

proteolysis. Many of these physiologically active proteins exist in the bloodstream in both precursor and active forms. We report here that proinsulin, a large polypeptide of 9,000 molecular weight, is rapidly hydrolysed by α_2 -macroglobulin-bound trypsin. This finding suggests that proteases bound to α_2 -macroglobulin may be involved in limited proteolytic cleavage associated with activation of precursor molecules as well as the degradation of biologically active polypeptides in the circulation.

Proinsulin was chosen as a model for investigation of the hydrolysis of polypeptide hormones by α_2 -macroglobulin-bound proteases because it is a polypeptide of known sequence¹ and representative size. Tryptic conversion of proinsulin to desalanyl insulin proceeds by way of two intermediate forms of proinsulin (insulin-Arg and insulin-Arg-Arg) with specific cleavages in the C-peptide region^{5,6}. Proinsulin, the intermediate forms, and desalanyl insulin can be resolved by polyacrylamide gel electrophoresis at pH 8.9 (ref. 4).

The digestion of porcine proinsulin (gift of Dr R. E. Chance, Lilly) was performed at 37 °C with an enzyme: substrate ratio of 1:200. A control incubation of proinsulin with α_2 -macroglobulin was included to assess the stability of proinsulin at 37 °C as well as the possible presence of endogenous protease-inhibitor complexes in the purified preparation of α_2 -macroglobulin. The gel electrophoresis pattern for digestion of proinsulin by α_2 -macroglobulin-bound trypsin or free enzyme is shown in Fig. 1. Chance *et al.*⁴ have shown that free trypsin rapidly digests proinsulin by way of two intermediate products to yield desalanyl insulin, which cannot be resolved from insulin in this gel electrophoresis system⁷. The intermediate forms seen in lanes 7–10 of Fig. 1 are presumed to be insulin-Arg and insulin-

Arg-Arg on the basis of previous investigations of the tryptic hydrolysis of proinsulin^{4–7}. The lighter appearance of the band for desalanyl insulin is due to some further digestion of trypsin, as well as to more rapid diffusion of smaller hydrolysis products from the gel, as can be seen by comparing the stain intensity of proinsulin (lane 1, 25 μ g) with that of insulin (lane 11, 50 μ g). By comparison of densitometer tracings of the proinsulin band at different times of hydrolysis, we estimate that proinsulin is digested by α_2 -macroglobulin-bound trypsin at approximately 10–15% of the rate of hydrolysis by the free enzyme.

Chance *et al.*⁴ have previously observed that trypsin hydrolyses proinsulin more rapidly than insulin or desalanyl insulin. The pattern of tryptic hydrolysis of proinsulin is also altered by binding of the enzyme to α_2 -macroglobulin (see Fig. 1). An intermediate product is apparent which is not present in detectable levels when proinsulin is digested with free trypsin. In addition, the major intermediate during digestion with trypsin does not accumulate to such a large extent during digestion with α_2 -macroglobulin-bound trypsin. This finding may reflect a more rapid diffusion of desalanyl insulin (molecular weight (MW) 5,600) and the intermediate products (MWs 6,050 and 5,900) compared with proinsulin (MW 9,000) into the enzyme-inhibitor complex.

Inactivation of the small peptide hormones angiotensin (MW 1,045) and lysine vasopressin (MW 1,116) by α_2 -macroglobulin-bound trypsin was reported previously⁸. Inactivation of these hormones involves proteolytic cleavage of two residues from the N terminal of the former peptide, while the latter is inactivated by cleavage of a C-terminal lysine amide, both of which might represent partial diffusion of a small peptide chain into the inhibitor-enzyme complex. In addition, plasmin bound to α_2 -macroglobulin has been

Fig. 1 Conversion of proinsulin to desalanyl insulin by α_2 -macroglobulin-bound trypsin. Lanes 1 and 2, proinsulin and α_2 -macroglobulin at 0 and 120 min; lanes 3–6, α_2 -macroglobulin-bound trypsin digestion of proinsulin at 15, 30, 60 and 120 min; lanes 7–10, trypsin digestion of proinsulin at 7, 15, 30 and 60 min; lane 11, insulin standard. Human α_2 -macroglobulin was purified from fresh plasma by DEAE-cellulose chromatography and gel filtration on Sephadex G-150 and Ultrogel ACA 22, a combination Agarose-polyacrylamide gel filtration resin (LKB). Bovine trypsin (Worthington) was treated with 1-tosylamido-2-phenylethylchloromethyl ketone to eliminate contaminating chymotryptic activity. Trypsin was pre-incubated with a 1.5-fold molar excess of α_2 -macroglobulin to produce an enzyme-inhibitor complex as follows: a 100- μ l aliquot of trypsin (0.1 mg ml⁻¹) was incubated with 300 μ l of α_2 -macroglobulin (1.2 mg ml⁻¹) in 40 mM Tris-HCl (pH 9.5) for 30 min at 37 °C. A control solution of enzyme and buffer was incubated in identical conditions. The extent of inhibition was measured using Remazol brilliant blue dyed hide powder (RBB-hide) as substrate as previously described¹⁰. Using this method, 0.1% of the original trypsin activity would have been detected. In the inhibition conditions used, however, no trypsin activity could be measured at 30 min, 2 h, or 24 h of incubation at 37 °C, while the control trypsin solution retained at least 90% activity after 24 h of incubation. Digestion mixtures consisted of a 40- μ l aliquot of the preincubation mixture of trypsin and α_2 -macroglobulin or trypsin alone with 100 μ l of proinsulin (2 mg ml⁻¹ in 40 mM Tris-HCl, 20 mM CaCl₂, pH 9.5). Sample aliquots (20 μ l) from the digestion mixtures were added to 16 mg of solid urea to form an 8 M urea solution and stored at -60 °C until electrophoresis. Polyacrylamide slab gel electrophoresis was performed at pH 8.9 using a modification⁷ of the original procedure described by Davis¹¹ in which 7 M urea was added to the resolving and stacking gels to improve resolution. The resolving gel contained 15% acrylamide with 0.4% *N,N'*-methylene-bis-acrylamide. Electrophoresis was performed for 16 h at 75 V in a BioRad Model 220 slab gel electrophoresis apparatus. Gel slabs were stained for 1 h in 0.1% amido black in 10% acetic acid, 20% ethyl alcohol and rapidly destained in 10% acetic acid to minimise diffusion of the peptide products from the gel. Using this procedure, the intensity of the bands remained constant for approximately 24 h.

shown to hydrolyse fibrinogen by degrading the A α -chain at a rate approximately 0.1% of that of the free enzyme¹. Our findings suggest that the inhibitor-enzyme matrix is substantially permeable to diffusion of peptides of moderate size. The tryptic cleavage position in proinsulin which produce desanyl insulin are at Arg-33 and Arg-63 in a polypeptide chain of 80 amino acid residues. Thus it seems that α_2 -macroglobulin-bound trypsin at approximately 10–15% variety of peptide hormones with molecular weights smaller than or comparable with that of proinsulin.

We have recently reported the presence of a pancreatic endopeptidase (elastase 2) in human blood and the elevation of this enzyme in sera of patients with acute pancreatic inflammation⁹. Pancreatic cationic trypsin has also been detected in human serum in this laboratory and will be the subject of a future communication. We suggest that some of the pathophysiological events associated with acute pancreatic inflammation may be due to hydrolysis of polypeptide hormones by circulating complexes of pancreatic proteases bound to α -macroglobulin.

Structural analysis of purified platelet-activating factor by lipases

PLATELET-activating factor (PAF) is a newly described mediator of anaphylaxis which has been implicated in the deposition of immune complexes in acute serum sickness in rabbits^{1–4}. It is released by leukocytes and tissues, most probably by the basophils or mastocytes from various mammalian species, under the influence of various substances known to activate these cells^{5,6}. The study of the chemical nature of the compound responsible for the PAF activity led us to the preparation of large amounts of PAF from hog leukocytes⁷. Several fractionation steps of the crude material yielded a highly active chloroform-soluble fraction. We usually started these procedures with 100 l of hog blood which yielded 100 l of PAF, the biological activity of which could be detected at the 1- μ l level. Nevertheless, we have not yet obtained sufficient homogeneous material to apply the current methods for structural analysis (mass spectrometry, magnetic nuclear resonance, hydrolysis reactions and so on). We therefore used different lipases to get some insight into the structure of PAF. We present here the results of these experiments which suggest that PAF is a 1-lyso-glycerophospholipid.

PAF was obtained by procedures described previously^{7,8} modified for use on bulk quantities of hog blood. Throughout the purification steps, PAF activity was detected by aggregation of rabbit platelets⁹, in the presence of 10 μ M indomethacin⁷. Briefly, leukocytes from 100 l of blood were prepared by differential centrifugations followed by sedimentation in 2.5% gelatin in Tris-buffered saline (TBS), pH 7.4. (TBS contained Tris (hydroxymethyl)-amino-methane, 1×10^{-2} M; NaCl, 1.37×10^{-1} M; pH adjusted to 7.4 or 8 with HCl. Tyrode's contained TBS plus MgCl₂, 1×10^{-3} M; CaCl₂, 1×10^{-3} M; KCl, 2.6×10^{-3} M.) PAF affixed to bovine serum albumin (BSA) was obtained by overnight incubation of the leukocytes in Tris-buffered Tyrode's at pH 9.5, containing 0.25% BSA. PAF-BSA (100 l) was exchanged in batch on to QAE-Sephadex-A50 at pH 9.5; PAF was then eluted by washing the beads with 80% and 100% ethanol. After concentration under vacuum, the ethanol-water residue was extracted with chloroform. The lipid (3–4 g) thus obtained was chromatographed on a silicic acid column developed with chloroform, chloroform-methanol mixtures, and pure methanol. PAF-active, phospholipid-rich (major phospholipids were phosphatidylcholine, sphingomyelin and lysophosphatidylcholine, as shown by thin layer chromatography (TLC) and chemical ionisation mass spectrometry), fractions eluted with pure methanol, were further purified by high pressure liquid chromatography on a silicic acid column (Varian, Micropak Si-5) with chloroform-methanol-water as solvent. The active fraction (1–2 mg of lipids) was eluted between sphingomyelin and lysophosphatidylcholine; it migrated between these phospholipids on silica gel TLC, with a solvent containing by volume 100 : 5 : 1 of CHCl₃ : CH₃OH : H₂O. (Development was by use of iodine, Dittmer⁸ or Dragendorff reagents.) Final recovery was 25% of starting activity.

Three preparations of PAF were treated with the lipases: (1) crude PAF-BSA, dialysed overnight against TBS; (2) the most active fraction obtained after the first silicic acid chromatography, which exhibited three or four spots on TLC; and (3), the purest fraction described above.

The lipases used in this study were lipase from *Rhizopus arrhizus*, phospholipases A2 from either porcine pancreas or *Crotalus*⁸, phospholipases C from *Bacillus cereus*⁹, and D from cabbage¹⁰. Dr Zwaal (from Van Deenen's Laboratory, Utrecht) kindly provided purified phospholipase A2 from *Naja naja* and *Crotalus* and a phospholipase C from *Staphylococcus aureus* specific for sphingomyelin (sphingomyelinase)¹¹.

The conditions and the results of the treatment of PAF with lipases are shown in Table 1. The phospholipases A2 (from various origins) and the phospholipases C and D completely abolished the ability of PAF (preparations 2 and 3) to aggregate rabbit platelets. In contrast, the lipase from *R. arrhizus*, which hydrolyses exclusively the fatty acid ester bond at the 1-position of phosphoglycerides^{12,13}, and sphingomyelinase C, were totally ineffective in this respect. It should be noted that PAF-BSA (preparation 1) was insensitive to the action of phospholipases A2, but fully sensitive to phospholipases C and D. Controls for optimal conditions for the action of lipases were hydrolysis of phosphatidylcholine or, for sphingomyelinase, sphingomyelin, followed by TLC. We also verified that PAF treated with phospholipases A2, C and D, in the presence of EDTA, not only retained its full activity, but also migrated on TLC with the same *R_f* as untreated PAF. Finally, the purest PAF fraction (preparation 3) was first treated with sphingomyelinase C, then exposed to lipase from *R. arrhizus* as well as to phospholipases A2 and C. The results were the same as those reported above, indicating that treatment with sphingomyelinase, besides not affecting PAF activity, does not seem to modify the structure of the molecule.

The lack of effect of lipase from *R. arrhizus* and the sensitivity of PAF to phospholipases A2, C and D seems to

Table 1 Action of lipases on PAF activity

Lipases (concentrations per ml)	Medium	PAF activity (units ml ⁻¹)
Lipase (<i>R. arrhizus</i>)* 0.1 mg	Borate 0.1 M pH 6.5 CaCl ₂ 10 mM Deoxycholate 1 mg ml ⁻¹ BSA 0.4 mg ml ⁻¹	148
A2 (Porcine pancreas* or <i>Crotalus</i>) 0.1 mg	TBS pH 8 CaCl ₂ 10 mM	0†
A2 (<i>N. naja</i>), purified† 0.05 unit	TBS pH 8 CaCl ₂ 10 mM	0†
A2 (<i>Crotalus</i>), purified† 0.5 unit	TBS pH 8 CaCl ₂ 10 mM	0†
C (<i>B. cereus</i>)* 0.001 mg	TBS pH 8 CaCl ₂ 10 mM	0†
D (cabbage)* 0.01 mg	Acetate buffer 0.1 M pH 5.6 CaCl ₂ 50 mM	0†
C (<i>S. aureus</i>)† Sphingomyelinase, purified 4 units	TBS pH 8 CaCl ₂ 10 mM MgCl ₂ 0.25 mM	136

Experimental conditions were 15 min incubation at 37 °C except for lipase from *R. arrhizus* which was incubated for 18 h at 30 °C with constant agitation and phospholipase D, incubated 1 h at 20 °C. These experiments were repeated five times with identical results. PAF activity is expressed in units, as defined in refs 3 and 6. Starting solution of PAF contained 140 units ml⁻¹.

‡ Same experiments done in the presence of 0.01 M EDTA: PAF activity was identical to that of starting solution.

favour PAF being a 1-lyso (or 2-acyl)-glycerophospholipid. Methylation by diazomethane for 10 min at room temperature¹⁴ did not affect the activity and the *R_f* of PAF, a result which suggests the presence of a choline polar head group. We therefore attempted to produce a PAF-like substance by hydrolysis of a variety of commercially available phospholipids with lipase from *R. arrhizus*, in order to obtain 1-lyso derivatives. We occasionally detected an aggregating activity shown to be due to production of arachidonic acid by its *R_f* on TLC and its inhibition by indomethacin. No PAF-like substance was obtained.

2-Acyl-glycerophospholipids are known to be unstable, and to isomerise to 1-acyl compounds¹⁵. This rearrangement, which occurs to some extent during chromatographic separation of the phospholipid, could account for the relatively low yield of our procedures, and could also represent an inactivation process of a potentially harmful mediator. The PAF-containing fraction, at the present state of purification, seems to be associated, in the chromatographic systems used, with sphingomyelin and lyso-phosphatidylcholine. The complete structure of PAF will be definitively known when more of the pure compound becomes available, making a more direct approach possible. But as the specificity for phospholipids of the enzymes used in this study is well established^{12,13} our present data leads us to postulate a phospholipidic structure for PAF, unique amongst the mediators of anaphylaxis.

New oncogenic papova virus from primate cells

THE taxonomic group of papova viruses comprises a number of small icosahedral virus species, all isolated from mammals. The members of this group, such as papilloma, polyoma and the so-called vacuolating Simian virus 40 (SV40) contain double-stranded circular closed DNA. All are oncogenic, capable of transforming cells *in vitro*. Some viruses of this group which are called BK¹ and JC² have been isolated from human patients—BK-virus is apparently widespread, as more than 80% of the human population harbour antibodies against this virus³. We describe here a new member of the papova virus group, designated HD-virus, which we have isolated in our laboratory from primate cells (VERO-cells—a permanent line derived from *Cercopithecus aethiops* monkey kidney cells⁴—which have been routinely passaged for several years in our laboratory). HD-virus is capable of rapidly transforming cells *in vitro*.

Electron micrographs of ultra-thin sections of the cells (Fig. 1) reveal particles that correspond in size and morphology to SV40, although their diameter seems slightly smaller.

Incubation of growing VERO-cells (1 d after seeding) with either ³H-thymidine or ³²P-orthophosphate leads to the synthesis of radioactively labelled superhelical HD-viral DNA which can be selectively isolated and purified in a dye buoyant density gradient⁵. Stationary cells (6 d after seeding) reveal, in contrast, a smaller amount of HD-DNA (one-fifteenth of the amount obtained 1 d after seeding of the cells). The size of HD-DNA was estimated by comparison with the electrophoretic mobilities of SV40 and BK-DNAs in Agarose gels to be equivalent to 5,100 base pairs (molecular weight 3.1 × 10⁶ compared with 3.6 × 10⁶ for SV40 DNA). Thus, the HD-DNA is smaller than SV40

Fig. 1 Electron micrograph of an infected VERO-cell. Inserts: micrographs of negatively stained virions released from infected cells by freezing and thawing and concentrated by centrifugation.

Fig. 2 Gel electrophoresis of DNA of HD, BK and SV40 virus. HD (a) and SV40 (b) form I and form II DNAs are shown in a and b. Fragments produced by digesting HD-DNA with *EcoRI* are depicted in c. A mixture of *HindII* + III was used to digest HD (d, g) BK- (e) and SV40-DNA (f). After electrophoresis the DNA was stained with ethidium bromide and photographs were taken under ultra violet light (a-e Agarose gel; f, g, polyacrylamide gel).

DNA by 14% (Fig. 2a, b). The susceptibility to various restriction endonucleases also distinguishes the HD genome from other papova virus genomes such as BK (Fig. 2e) and SV40 (Fig. 2f). One double-strand cut is produced by endonuclease *HindII* while two cuts are made by the enzymes *HindIII*, *EcoRI* (Fig. 2c) *HpaI* and *HpaII*. On the other hand, HD-DNA is not attacked by endonuclease *BamHI*. The molecular sizes of the three HD-DNA fragments shown in Figs 2d, g are 1.90 , 0.70 , and 0.50×10^6 respectively. Treatment with restriction enzymes and gel electrophoresis were performed as before⁶.

Unlike BK, JC, polyoma, and SV40 which all share some base-sequence homology with each other^{8,9,10} HD-virus proved in DNA-DNA hybridisation studies to be unrelated to the other viruses (Table 1). Using the stringent conditions of hybridisation in $2 \times \text{SSC}$ and 50% formamide at 37°C we found, in agreement with the data of others⁸, 10–16% homology between BK and SV40, while HD and SV40 displayed only 1.2% homology. BK and HD-DNA show as little as 0.2% homology. We were unable to demonstrate any homology between HD and polyoma virus in these conditions. Furthermore, anti-SV40 T antigen and

anti-SV40 capsid sera fail to react with HD-infected VERO-cells as judged by immunofluorescence.

VERO-cells which harbour HD-virus do not display any recognisable cytopathogenic effect (c.p.e.). They are routinely passaged at a weekly 1:4 split ratio in minimum essential medium (MEM) supplemented with 10% calf serum. Because of the lack of c.p.e. we have not been able yet to establish a plaque assay for titration of the HD-virus. Thus far we have been using the synthesis of HD-superhelical FO I DNA as a measure of infectivity. Using this assay it could be shown that lysates of our VERO-cells that were obtained after freezing and thawing followed by DNase and ether treatment retained the ability to induce the synthesis of HD-FO I DNA. For this purpose 10^7 VERO-cells were frozen and thawed twice in 50 ml of MEM, the cellular debris was removed by centrifugation (10 min, 4,000 r.p.m., Christ Heraeus Minifuge), and $100 \mu\text{g}$ of pancreatic DNase (Serva) were added for 60 min at 37°C after adjusting the medium to 10 mM MgCl_2 . Then an equal volume of ether was added, the mixture was shaken for 5 min, and the medium was separated from the ether. Residual ether was removed by bubbling N_2 through the solution. Ten ml, representing one-fifth of the virus-containing solution were used after passing it through a Millipore

Fig. 3 Soft agar assays of a, uninfected VERO-cells (McMaster) and b, the same cells after infection with cell lysate containing HD-virus.

Millex filter (pore diameter $0.22 \mu\text{m}$) for infection of approximately 10^7 cells (1-h adsorption time). Four days later the cells were labelled with ^3H -thymidine ($500 \mu\text{C}$ per 50 ml) for 1 d and the superhelical DNA was purified as before. We found that HD-DNA replicates, although poorly, in RITA cells, another permanent line derived from *Cercopithecus aethiops* (Italdiagnostics). Other cell lines such as 3T3, WI38, CV-1 and human embryonic lung proved to be non-permissive for the replication of HD-DNA.

To test whether VERO-cells that have been maintained in other laboratories also contain HD-virus or HD-viral DNA we have attempted to label such cells using the procedure described above. We were unable to demonstrate the presence of HD-FO I DNA in VERO-cells from the Institute for Virology, Universität Erlangen, and from the Department of Pathology, McMaster University, Hamilton, Ontario. VERO-cells from McMaster University totally lack HD-DNA and fail to grow in soft agar¹¹. VERO-cells grown in our laboratory contain HD-DNA and 0.1–0.5% grow to form colonies in soft agar. When the Canadian VERO-cells were infected with lysate of our VERO-cells (prepared as described above) about 1% of the cells formed colonies in soft agar (Fig. 3). The number of colonies was not increased by doubling or tripling the virus-containing inoculum. This

Table 1 DNA-DNA hybridisation between HD and other papova DNAs

³ H-DNA in solution	DNA on filter (1 μg)	³ H-c.p.m. input	³ H-c.p.m. bound	% Bound to filter*
HD	SV40	9×10^4	0	0
	BK		200	0.2
	HD		56,300	62.4
SV40	SV40	1.29×10^5	75,500	58.5
	BK		21,040	16.3
	HD		1,602	1.2
BK	SV40	6.5×10^4	6,950	10.7
	BK		49,460	76.0
	HD		0	0
Polyoma	SV40	2.2×10^4	250	1.1
	BK		0	0
	HD		0	0

Viral DNAs were labelled⁶ and purified⁶ and filter hybridisation assays⁷ were performed essentially as before.

*Corrected for nonspecific binding to T4-DNA.

might be explained by the presence of a limited number of cells, which are capable of responding to infection with the formation of colonies in soft agar. Between 0.7 and 1% of the infected cells grew to form colonies in medium containing 2% calf serum. Only 0.04% of the uninfected cells gave rise to colonies in the same conditions. This indicates a reduced serum requirement for the infected cells^{12,13}. We believe, therefore, that HD-virus can transform VERO-cells.

We have thus isolated what seems to be an entirely novel papova virus and we intend to screen human and other tumours for evidence of its distribution.

We thank K. Bosslet, T. de Ledezma, M. Pernfuss and C. Waldeck for technical assistance and J. Tooze for help in preparation of the manuscript. This work was supported by a grant of the Bundesminister für Forschung und Technologie.

Note added in proof: While this paper was in press we have found that there exists an additional size class of HD-FO I DNA which is by 6% larger than the HD-DNA described here.

Type C RNA virus production and cell competence for normal differentiation in myeloid leukaemic cells

STUDIES with various species have shown that type C viral genomes can be integrated and vertically transmitted as chromosomal elements within the cellular genomes (for review see refs 1-6) and that nucleic acid sequences derived from these viruses can be detected in the DNA⁷⁻¹⁰ of normal cells (for review see ref. 11). It has been suggested that in addition to their role in tumour formation, type C RNA viruses may also have a role in normal cell differentiation^{2,3}. We suggest here that one way in which these viruses may influence differentiation, is by modifying the competence of cells to be induced to differentiate by a normal regulator.

Normal differentiation-inducing regulators have been identified in cells of the haematopoietic system and these include the protein erythropoietin¹² which induces differentiation of erythrocytes and the protein that we now call MGI (macrophages and granulocyte inducer) (refs 13, 14) which induces differentiation of macrophages and granulocytes^{13,15-18}. The isolation of clones of haematopoietic cells with different degrees of competence for differentiation by one of these proteins, should be a useful experimental system to test the relationship between type C RNA viruses and cell competence for differentiation by a specific regulator. We have isolated such clones from

mouse myeloid leukaemia, which differ in their competence to be induced to differentiate by MGI (refs 13, 19-23). One type of clone, MGI⁺D⁺, can be induced by MGI to undergo normal cell differentiation, including the formation of rosettes for cell surface Fc and C3 receptors^{20,21}, the synthesis and secretion of lysozyme²² and differentiation to mature macrophages and granulocytes^{13,19}. A second type of clone, MGI⁺D⁻, can be induced for Fc and C3 rosettes and lysozyme but not to differentiate to mature cells and a third type, MGI⁻D⁻, was not inducible for any of these properties (Table 1). Some, but not all the properties associated with cell differentiation can also be induced in some of these myeloid leukaemic clones by the steroid hormones dexamethasone, prednisolone or oestradiol^{20,21,24} and compounds such as cytosine arabinoside, actinomycin D, 5-iododeoxyuridine²⁰ or dimethylsulphoxide²². The protein inducer¹³⁻¹⁸ that we call MGI has also been referred to by others as colony stimulating factor²³ or activity²⁰. We show here that the competence of myeloid leukaemic clones to be induced to differentiate to mature macrophages and granulocytes by the normal regulator MGI, is associated with a higher production of type C virus.

Table 1 Competence for the induction of differentiation in clones of myeloid leukaemic cells by the differentiation-inducing protein MGI

Cell type	Clone numbers	Inducibility by MGI			
		Rosettes Fc	Rosettes C3	Lysozyme	Mature macrophages and granulocytes
MGI ⁺ D ⁺	9,11,12	+	+	+	+
MGI ⁺ D ⁻	5,13,19	+	+	+	-
MGI ⁻ D ⁻	1,6,10	-	-	-	-

(+), Inducible, (-), non-inducible. Cells were incubated with conditioned medium containing MGI as described²³. MGI⁺D⁺ clones 9,11,12 and MGI⁺D⁻ clones 5,13,19 (refs 20, 21) were derived from a myeloid leukaemia originating in a SL mouse²⁶. MGI⁻D⁻ clones 1,6,10 (refs 21-23) were derived from three independently induced myeloid leukaemias after X-ray irradiation of SJL/J mice. Before treatment with MGI, cells from all the clones grew in suspension as myeloblasts to promyelocytes and produced myeloid leukaemia after inoculation into isologous adult mice. The cells were cultured in Eagle's medium with a fourfold concentration of amino acids and vitamins (H-21, GIBCO) and 10% inactivated (56 °C, 30 min) foetal calf serum.

All the nine clones tested of the three types shown in Table 1 were found to be producing type C virus. Typical type C particles were observed by electron microscopy in sections of the cultured cells and at a buoyant density of 1.15gcm⁻³ in a sucrose equilibrium density gradient of pellets from the culture medium. To quantitate the amount of virus released by the different clones, we measured the reverse transcriptase activity⁴ of partially purified and concentrated virus pellets obtained from the culture fluids²⁸. The virus production measured by this enzyme activity with the template oligo(dT):poly(rA), and cellular growth rate of three clones representative of the different types of myeloid leukaemic cells are shown in Fig. 1. The MGI⁺D⁺ and the MGI⁺D⁻ clones had similar growth rates, while the MGI⁻D⁻ clones grew somewhat faster. Virus production in all the clones was not significantly different for the first 2 d after seeding. When the cells entered the logarithmic phase of growth, however, virus production increased 16-fold in the MGI⁺D⁺ clone and only 2-fold in the MGI⁺D⁻ and MGI⁻D⁻ clones. Optimum virus production was obtained with all three types of clones at day 4 and then declined when the cells approached the stationary phase of growth. A similar relationship between type C RNA virus production and cellular growth has been observed in cultures of

Fig. 1 Reverse transcriptase activity in the tissue culture medium (a) and number of cells (b) at different days after seeding of the three types of myeloid leukaemic clones. ▲, MGI⁺D⁺ clone 9 and ●, MGI⁺D⁻ clone 5 were seeded at 4×10^5 cells and ○, MGI⁻D⁻ clone 6 at 2×10^5 cells per 10-cm Nunc tissue culture Petri dish in 10 ml modified Eagle's medium (see Table 1) and 10% inactivated foetal calf serum. To assay for reverse transcriptase activity⁴, the cells were pelleted from 20 ml of medium and the medium clarified of cell debris²⁸ by centrifugation at 10,000 r.p.m. in a SS-34 rotor in a RC-5 Sorval centrifuge at 4 °C. The clarified medium was layered on a 5-ml cushion of 20% (v/v) glycerol in TNE buffer (0.1 M NaCl, 0.01 M Tris pH 7.6, and 0.001 M EDTA) and centrifuged at 40,000 r.p.m. for 60 min in a 60Ti type rotor at 4 °C in a Beckman ultracentrifuge. The resultant pellets were suspended in 0.1 ml TNE buffer. Enzyme activity was measured using [the synthetic template oligo(dT):poly(rA)] (Collaborative Research). Oligo(dT) and poly(rA) were pre-annealed at a ratio of 1:10 in 0.15 M NaCl, 10 mM Tris-hydrochloride (pH 7.8) at 37 °C for 5 min. Enzyme reaction mixtures (50 µl) consisted of 2 µM Tris (pH 7.8) 6 µM NaCl, 0.1 µM MnCl₂, 0.4 µM DTT, 0.015% NP/40, 5 µg oligo(dT):poly(rA), 0.001 µM unlabelled TTP, 2 µCi H³-dTTP, and 10 µl of the suspended virus pellet in TNE buffer. Reactions were carried out for 30 min at 37 °C and terminated by addition of 0.1 ml 0.2 M sodium pyrophosphate and 1 ml 10% trichloroacetic acid. Samples were collected on 0.45 µm Millipore filters rinsed with 5% cold trichloroacetic acid and counted in a toluene-based scintillation fluid in a Tri-carb Packard fluid scintillation counter. The values represent the means of three independent experiments.

other cell types²⁹⁻³². Since virus production in our experiments reached an optimum at day 4, all the following experiments were carried out on the fourth day after seeding.

Studies with the 9 clones have shown (Fig. 2), that only the three MGI⁺D⁺ clones, which can be induced to differentiate to mature macrophages and granulocytes, produced high levels of virus, while the partially inducible MGI⁺D⁻ and the non-inducible MGI⁻D⁻ clones produced lower levels of virus. The amount of virus produced by the MGI⁺D⁺ clones was about 4-5-fold higher than the highest amount produced by any of the MGI⁺D⁻ or MGI⁻D⁻ clones (Fig. 2). Three subclones isolated from MGI⁺D⁺ clone 9 and three subclones from MGI⁺D⁻ clone 5 were assayed for reverse transcriptase activity. All the MGI⁺D⁺ subclones showed the same high enzyme activity in the culture medium as the parental clone 9, while all the MGI⁺D⁻ subclones showed the lower enzyme activity of the parental clone 5.

The higher enzyme activity in the culture fluids from MGI⁺D⁺ clones was further identified as type C virus reverse transcriptase, by sucrose equilibrium density gradient centrifugation of the partially purified virus preparations from the three types of myeloid leukaemic clones. The peak of the reverse transcriptase activity at the buoyant density of 1.15 g cm^{-3} was 10-fold higher with MGI⁺D⁺ clone 9 than with MGI⁺D⁻ clone 5 and MGI⁻D⁻ clone 6. The virus specific nature of the enzyme was also confirmed by using, in addition to oligo(dT):poly-

(rA), two other synthetic templates, oligo(dG):poly(rC), a viral specific template, and oligo(dT):poly(dA), which is utilised poorly by the viral RNA directed DNA polymerase and is a good template for the cellular DNA-DNA polymerases³³⁻³⁶ (for review see ref. 37). The results have shown that with pellets obtained from culture fluids of all the 9 clones, the highest activity with oligo(dG):poly(rC) was again found with the MGI⁺D⁺ clones and there was almost no activity with oligo(dT):poly(dA). Incubation of cells for 1 d with 50 units of purified mouse interferon (from Dr I. Gresser, Institut de Recherches Scientific sur le Cancer, Villejuif), gave 70%-80% reduction in the enzymatic activity that could be recovered from the culture medium. This is in agreement with previous results showing that interferon can inhibit the secretion of type C virus³⁸⁻⁴⁰, and provides additional evidence for the viral nature of the activity measured.

Indirect immunofluorescence tests⁴¹ with an antiserum against murine leukaemia virus group-specific (MULV-gs) antigens (from Dr M. Haas⁴²) showed that all three types of clones were positive for these viral antigens and that all the cells were stained. After acetone fixation, MGI⁺D⁺ clones seemed to be the most brightly stained and titration of MULV-gs antigens by absorption of immunofluorescence with cell extracts⁴² has indicated, that the MGI⁺D⁺ clones had a higher amount of MULV-gs antigens. Unfixed cells tested for cap formation also showed a higher frequency of caps for MULV-gs antigens on MGI⁺D⁺ cells (Table 2).

Table 2 MULV-gs antigens. Titre of cell extracts tested by immunofluorescence absorption, and cap formation on unfixed cells

Cell type	Clone no.	Immunofluorescence absorption, antigen dilution of cell extracts						% Cells with cap
		0	1:2	1:4	1:8	1:16	1:32	
MGI ⁺ D ⁺	9	—	—	—	—	++	+++	90±5
MGI ⁺ D ⁻	5	—	—	+	++	+++	+++	10±3
MGI ⁻ D ⁻	6	—	+	++	+++	+++	+++	2±1

MULV-gs antigen titre of cell extracts was tested by absorption of immunofluorescence. Cells at 4 d after seeding were sonicated in Earl's balanced salt solution to give a 20% cell extract. Serial dilutions of this extract (40 µl) were then incubated overnight with an equal volume of Lewis rat anti-MULV-gs antiserum⁴² at 4 °C. Residual immunofluorescence after incubation with fluorescent rabbit anti-rat IgG (Miles Yeda) was scored on an acetone fixed NIH/3T3 Moloney virus producing mouse cell line on a scale from —(no immunofluorescence) to +++ (strong immunofluorescence obtained without absorption). Absorption tests were performed with a concentration of antiserum (1:32) two doubling dilutions below the end-point for the acetone fixed NIH/3T3 Moloney virus producing mouse cells. Cap formation on cells 4 d after seeding was tested after incubation of unfixed cells with rat anti-MULV-gs antiserum (1:8) for 15 min and then for 30 min with fluorescent rabbit anti-rat IgG. There was no immunofluorescence after incubation with normal rat serum instead of the anti-MULV-gs antiserum.

Our results show that mouse myeloid leukaemic cells that can be induced to differentiate to mature macrophages and granulocytes by the normal inducer protein MGI, produced a higher amount of type C RNA virus than clones of myeloid leukaemic cells that can be only partially or not at all induced to differentiate by this normal regulator. The amount of virus production was, therefore, associated with the competence of the leukaemic cells to undergo differentiation to normal mature cells. It will be of interest to identify the virus or viruses produced. Type C RNA viruses have been observed in myeloid leukaemic cells from human and rats⁴³⁻⁴⁵, and it will also be of interest to determine in these two other species, the relationship between the amount of virus production and ability of the cells to be induced to differentiate by the normal regulator MGI.

Fig. 2 Reverse transcriptase activity in the culture fluids of nine myeloid leukaemic clones. MGI⁺D⁺ clones 9,11,12 (c) and MGI⁺D⁻ clones 5,13,19 (b) were seeded at 4×10^5 cells and MGI⁻D⁻ clones 1,6,10 at 2×10^5 cells (a) per 10-cm tissue culture Petri dish. The culture medium was collected 4 d after seeding and reverse transcriptase activity measured as described in the legend to Fig. 1. The means and standard errors are based on six independent experiments.

Friend erythroleukaemic cells can be induced to differentiate partially by dimethylsulphoxide⁴⁶ and some other polar compounds⁴⁷ and the competence for this partial induction of erythroid differentiation was not associated with the amount of virus production³². However, the erythroleukaemic cells studied had lost the ability to respond to erythropoietin⁴⁸, the normal regulator of erythroid cell differentiation, whereas the MGI⁺ myeloid leukaemic cells, including those that can respond to dimethylsulphoxide²², have not lost the ability to respond to MGI, the normal regulator of differentiation to macrophages and granulocytes. It may also be that the viruses produced by the Friend erythroleukaemic cells differ from those produced by the myeloid leukaemic cells and that not all type C viruses are related to cell competence for differentiation.

One possible explanation for the relationship that we have found in our myeloid leukaemic cell system may be the association of viral sequences with regulatory sites for differentiation. The increased virus production could then indicate a different state of the regulatory sites in the competent compared with the non-competent cells. The higher virus production by the competent cells could either be a by-product or directly influence these regulatory sites. Another possibility is that the increased virus production by the competent cells is associated with an appropriate arrangement of surface receptors for MGI that is required for the induction of normal cell differentiation. The differences in cap formation by MULV-antigens (Table 2) and con A (refs 13, 49) indicate that it will be of interest to determine whether, as in cells transformed by sarcoma viruses⁵⁰, there are also differences in receptors for other polypeptide hormones. The myeloid leukaemic clones used in our studies seem to be a particularly favourable experimental system to investigate further these possibilities of the role of type C viruses in relation to cell competence for differentiation by a normal receptor.

We thank Dr M. Haas for help in experiments using anti-MULV-gs antiserum and Mrs Haya Dorf for technical assistance.

Post-transcriptional control of avian oncornavirus transforming gene sequences in mammalian cells

TRANSFORMATION of cells by RNA tumour viruses generally results in a stable association of the viral genome with the morphologically altered cell. Studies with temperature-sensitive mutants of these viruses have clearly demonstrated that viral-specific gene functions are required for establishment and maintenance of the transformed phenotype¹⁻⁶. For avian oncornaviruses the transforming (sarcoma) gene sequences are required for both transformation of cells in tissue culture and the production of tumours in animals⁷⁻⁸. In all of the oncornavirus-infected mammalian cell systems studied to date regulation of expression of the avian RNA tumour virus transforming gene sequences seems to be under the influence of transcriptional control mechanism(s) because appreciable differences in the amount of sarcoma-specific RNA can be detected in cells exhibiting normal and transformed phenotypes. For instance, the amount of sarcoma-specific RNA was substantially reduced in most revertant subclones of Rous sarcoma virus (RSV)-infected hamster cells compared with the original transformed clones⁹⁻¹¹. Although several revertant RSV-hamster cells exhibited less dramatic differences in sarcoma-specific RNA, it nevertheless seemed that the transformed

phenotype was directly related to the extent of transcription of the virus transforming gene sequences in this transformed/revertant cell system. A similar correlation between the amount of sarcoma-specific viral RNA and the malignant phenotype was recently reported for murine sarcoma virus-infected cells¹².

Here we present data indicating that mammalian cells may also regulate the expression of viral transforming gene sequences by post-transcriptional mechanisms. This conclusion is based on the observation that revertant subclones of RSV-infected field vole cells contain as much, if not more, sarcoma-specific RNA as the transformed cells from which they were derived. Our preliminary data also indicate that the post-transcriptional restriction of expression of viral transforming genes in revertant vole cells does not result from either selective transport of sarcoma-specific RNA from the nucleus to the cytoplasm, or the lack of association of this RNA species with polyribosomes.

An established diploid cell line from the European field vole, *Microtus agrestis* was transformed by the Schmidt-Ruppin strain of Rous sarcoma virus (SR-RSV) by Dr P. Vogt of the University of Southern California. The procedures for the isolation of clones of RSV-transformed mammalian cells and revertant subclones have been described elsewhere^{13,14}. The morphology of typical normal, transformed, and revertant vole cell types can be seen in Fig. 1. Not only did the revertant subclones resemble normal cells in their 'flat' fibroepithelial-like morphology but they also failed to grow in soft agar (R. Krzyzek, unpublished observations).

We have previously demonstrated that both transformed and revertant field vole cells contain similar genome-equivalents of virus-specific DNA¹⁵. These studies were performed by determining the influence, if any, that unlabelled DNA from RSV-transformed, and reverted vole cells has on the reassociation kinetics of the more complex double-stranded DNA component synthesised by the RSV RNA-directed DNA polymerase *in vitro*¹⁶. However, these methods cannot completely exclude the possibility that a small portion (<20%) of the viral genome is deleted from the DNA of the reverted cell because the virus-specific DNA probe used in these studies may not represent the entire viral genome¹⁶. Consequently it was conceivable that the reversion phenomenon could result from the complete or partial deletion of the RSV-transforming gene sequences. To determine whether the RSV-transforming gene sequences were retained in vole cells during reversion we have

performed further hybridisation analysis with a specific radiolabelled DNA probe complementary to the RSV-transforming gene sequences (cDNA_{src})¹⁷. As shown in Table 1 the cDNA_{src} probe hybridises equally well with DNA obtained from either transformed or revertant field vole cells. The extent of hybridisation is not complete in our conditions of hybridisation even with DNA from RSV-transformed avian cells. The reason for this is not clear; however this problem is not unique to our situation but has been observed by other investigators as well¹⁸. Even if complete hybridisation was achieved, this would not negate the possibility that the transforming gene in the revertant cell type was inactive due to a very small gene deletion or a point mutation which would not be detectable by the hybridisation techniques used. Therefore we performed studies to determine whether the transforming gene sequences present in the revertant vole cells were biologically active and capable of inducing transformation. As indicated in Table 2, the entire infectious RSV(D) genome could be rescued from transformed and revertant cells by either fusion with permissive cells or transfection of avian cells with DNA purified from both cell types. Although we have not computed precise frequencies of rescue, the efficiency of rescue of virus from transformed and revertant cells by both techniques was quite similar.

Table 1 Hybridisation of cDNA_{src} to transformed and revertant field vole cell DNA

Source of cellular DNA	Hybridisation (%)
RSV-infected duck	49.5
RSV-transformed field vole	
Clone 1	43.0
Clone 22	33.0
Revertant field vole	
Subclone 866	42.0
Subclone 4	44.6
Field vole liver	0.0

Cellular DNA was prepared as previously described¹⁹ and fragmented to a length of 300–400 nucleotides by treatment with 0.3 N NaOH for 30 min at 100 °C. Hybridisation analysis was performed in 30- μ l reaction volumes containing 0.6 M NaCl, 0.02 M Tris-HCl (pH 7.4) 0.002 M EDTA, 0.05% SDS, ³H-cDNA_{src} (1,500 c.p.m.) and a vast excess of fragmented, denatured cellular DNA (12 mg ml⁻¹) to C₀t values of approximately 5×10^4 mol s l⁻¹. All reactions were incubated for 70 h at 68 °C and the extent of hybridisation was determined by resistance to S₁ nuclease^{20,21}. % hybridisation was corrected for the intrinsic S₁ nuclease-resistance of cDNA_{src} (13.0%).

Since the revertant vole cells contain the entire biologically active sarcoma virus genome, it was of interest to determine whether an alteration in the transcriptional expression of the proviral DNA genome was responsible for phenotypic reversion. Our previous studies had indicated that revertant field vole cells contained similar amounts of virus-specific RNA as the transformed cell types (R. Krzyzek, A.F.L., P. Vogt & A.J.F., submitted for publication). The cDNA probe used in these studies was a relatively uniform representation of the viral RNA genome and indicated that the bulk (~70%) of the RSV-specific nucleotide sequences were expressed as virus-specific RNA in both transformed and revertant cells. However, this probe was not sufficiently sensitive to determine whether differences in transcription of the viral transforming gene occurred in these cell types. Therefore, to determine directly the expression of the RSV-transforming gene sequences in transformed and revertant vole cells we used the ³H-labelled cDNA_{src} probe to quantitate sarcoma-specific RNA in these cells. From Fig. 2 it can be seen that the rates of hybridisation of the cDNA_{src} probe to total cell RNA obtained from both transformed and revertant field vole cells was not appreciably different,

Fig. 1 Morphology of RSV-transformed and revertant field vole cells. *a*, Normal field vole cells; *b*, RSV-transformed field vole cells (clone 1); *c*, Revertant field vole cells (subclone 866); *d*, RSV-transformed field vole cells (clone 22); *e*, Revertant field vole cells (subclone 4). All photographs were taken at 80 \times magnification.

Table 2 Rescue of Rous sarcoma virus from transformed and revertant field vole cells by DNA transfection and Sendai virus-mediated fusion with susceptible chicken cells

Cell type	Transfection	Sendai virus-mediated fusion
RSV-transformed field cells		
Clone 1	+	+
Clone 22	ND	+
Revertant field vole cells		
Subclone 4	ND	+
Subclone 866	+	+
Uninfected field vole cells	-	-

Cellular DNA was prepared from field vole cells by the method of Haase *et al.*²². Transfections were performed by coprecipitation of DNA with calcium phosphate^{23,24}. Briefly, DNA dissolved in *N*-2-hydroxyethylpiperazine-*N'*-2-ethanesulphonate (HEPES)-saline-phosphate buffer at 20 $\mu\text{g ml}^{-1}$ was adjusted to 0.125 M CaCl_2 and allowed to precipitate at room temperature for 30 min. Aliquots (0.5 ml) of the DNA-calcium phosphate mixture containing approximately 10 μg of DNA were then added to chick secondary fibroblasts ($0.5\text{--}10^6$ cells per 60-mm tissue culture plate) previously washed twice with (HEPES)-saline-phosphate buffer. After 30 min incubation at room temperature, 2.5 ml of growth medium containing 10% calf serum but without tryptose phosphate broth was added to the cultures which were then incubated for 4 h at 37 °C. The growth medium containing the DNA-calcium phosphate mixture was then removed and replaced with growth medium containing tryptose-phosphate broth with 10% calf serum. Foci of transformed cells appeared within 10 to 14 d. When revertant or RSV-transformed field vole cell DNA was treated with pancreatic DNase (10 $\mu\text{g ml}^{-1}$, 30 min at room temperature) before the addition of CaCl_2 , no transformation of chick fibroblasts was observed.

Rescue of RSV from field vole cells by Sendai-mediated fusion with chick fibroblasts was performed as described by Boettiger²⁵. The procedure involved adding 0.1 ml of β propiolactone-inactivated Sendai virus (200–400 haemagglutination units) to cultures of chick secondary fibroblasts ($0.5 \times 10^6\text{--}1.0 \times 10^6$ cells per 35-mm tissue culture plate) previously washed twice with cold growth medium without serum. The cultures were then incubated for 15 min at 4 °C, with cold growth medium without serum and 0.1 ml containing 5×10^6 field vole cells previously treated with mitomycin C (10 $\mu\text{g ml}^{-1}$, 2 h at 37 °C) was added. After incubation for 40 min at 37 °C, growth medium was added containing 10% calf serum. Foci of transformed cells appeared within 4–7 d after fusion. No transformation was observed if treatment of chick fibroblasts with Sendai virus was omitted. Coincident with the appearance of foci was the production of virus as assayed by particle count and focus formation. Identification of the virus as RSV subgroup D was accomplished serologically by demonstrating that infectivity of the rescued virus was neutralised by RSV-D-specific antisera.

ND, Not done.

indicating the presence of similar amounts of sarcoma-specific RNA in both cell types. In fact revertant subclone 866R actually contained more sarcoma-specific RNA than both the transformed clones. Furthermore, the maximum hybridisation achieved from both cell types was identical, indicating that similar extents of transcription of the sarcoma-specific sequences had occurred in transformed and revertant cells. The extent of hybridisation with RNA from transformed and revertant field vole cells was identical to that observed with both RNA from transformed permissive cells and purified 70S RNA from the same strain of RSV used to synthesise the cDNA_{src} probe. No hybridisation to the cDNA_{src} probe was observed with RNA from normal field vole cells (Fig. 2).

In an effort to determine whether the sarcoma-specific RNA sequences were distributed similarly in transformed and revertant field vole cells, nuclear, cytoplasmic and polyribosomal RNA from these cells were hybridised to the cDNA_{src} probe (Figs 3 and 4). The rates of hybridisation obtained with the nuclear and cytoplasmic fractions indicated that the amounts of sarcoma-specific RNA present in the revertant cells were no less than that found in the corresponding fractions of the transformed cells. Thus it seems unlikely that the reverted state is related to an alteration in the intracellular localisation of sarcoma-specific RNA in these cells. Similar results were obtained for RNA isolated from polyribosomes

from both cell types indicating that the same amount of sarcoma-specific RNA is associated with polyribosomes in the revertant and transformed field vole cells (Fig. 4).

The hybridisation analyses presented above between RNA from transformed and revertant vole cells and a cDNA probe representing sarcoma-specific RNA sequences indicate that the phenomenon of reversion in these cells is not a function of transcriptional regulation of the

Fig. 2 Detection and quantitation of sarcoma-specific RNA¹ in transformed and revertant field vole cells. Total cellular RNA was extracted from vole cells with sodium dodecyl sulphate-phenol at 56 °C as previously described²⁶. Nucleic acids were precipitated with ethanol and collected by centrifugation at 13,000g for 30 min. The pellets were dissolved in DNase buffer (0.01 M Tris-HCl (pH 7.4), 0.01 M MgCl_2 at a concentration of 0.5 to 1.0 mg ml^{-1} . Residual DNA was removed by digestion with 20 μg of RNase-free pancreatic DNase ml^{-1} for 2 h at room temperature²⁷. The preparations were then adjusted to 0.01 M EDTA, 0.1 M Tris-HCl (pH 9.0), 0.5% SDS, extracted three times with two volumes of phenol-chloroform-isoamyl alcohol (50:50:1), precipitated twice with ethanol, and resuspended in TE buffer (0.02 M Tris-HCl, pH 7.4, 0.01 M EDTA). The conditions for the synthesis of virus-specific DNA *in vitro* with detergent-activated RSV are essentially those described by Stehelin *et al.*¹⁷. Reaction mixtures contained 200 $\mu\text{g ml}^{-1}$ of virus protein; 0.1 M Tris-HCl (pH 8.1); actinomycin D (100 $\mu\text{g ml}^{-1}$); 0.008 M MgCl_2 ; 2% (v/v) β -mercaptoethanol; unlabelled dATP, dCTP and dGTP (each 2×10^{-4} M); ^3H -dTTP (6.6×10^{-6} M, 0.33 mCi ml^{-1}); and Nonidet P-40 (0.08% v/v). After incubation for 4 h at 37 °C, the reaction mixture was supplemented with the addition of unlabelled dATP, dCTP, and dGTP to 4×10^{-4} M, further incubated for 12 h and then terminated by the addition of EDTA to 0.01 M. The enzymatic product was extracted with SDS-Pronase-phenol, treated with 100 $\mu\text{g ml}^{-1}$ pancreatic RNase for 1 h at 37 °C in 0.003 M EDTA to disrupt RNA:DNA hybrids, re-extracted with SDS-Pronase-phenol and concentrated by ethanol precipitation. cDNA complementary to the RSV transforming gene sequences (cDNA_{src}) was then purified from the total viral-specific DNA product by selective hybridisation to avian leukosis virus essentially as described by Stehelin *et al.*¹⁷. The transformation specific nature of this probe was confirmed by demonstrating that cDNA_{src} hybridises to transforming sarcoma virus RNA but not to non-transforming leukosis virus RNA. Hybridisation of ^3H -labelled cDNA_{src} to vole cell RNA was performed in a 10- μl reaction mixture containing 0.01 M Tris-HCl (pH 7.4), 0.6 M NaCl, 0.001 M EDTA, single-strand ^3H -cDNA (1,500 c.p.m.), 1.0 mg ml^{-1} yeast tRNA and the indicated amount of RNA. The reaction mixtures were sealed in 30- μl microcaps and incubated for either 24 or 70 h at 68 °C. Hybrid formation was detected by treatment of samples with single-strand specific S_1 nuclease^{20,21}. The results of hybridisation analysis were expressed as a function of $C_r t$ (concentration of RNA in $\text{mol l}^{-1} \times$ time of incubation in s). The percent hybridisation was corrected for the intrinsic S_1 nuclease resistance of cDNA_{src} (13%) and normalised to 100% values (actual hybridisation averaged 70–75%). Each point represents the average of three separate determinations. \square , RNA 70S RNA; \blacksquare , RSV-transformed duck cells; \circ , RSV-transformed field vole clone 1; Δ , RSV-transformed field vole clone 22; \blacktriangle , revertant field vole subclone 4; \bullet , revertant field vole subclone 866; \triangle , uninfected field vole; \odot , avian leukosis virus 70S RNA.

Fig. 3 Detection and measurement of sarcoma-specific RNA in the nucleus and cytoplasm of transformed and revertant field vole cells. Nuclear and cytoplasmic RNA from vole cells was prepared as follows. Frozen cell pellets were thawed rapidly at 37 °C and resuspended in RSB buffer (0.01 M Tris-HCl (pH 8.3), 0.01 M NaCl, 0.0015 M MgCl₂) at approximately 5×10^7 cells ml⁻¹. The cell suspension was adjusted to 0.5% Nonidet P-40, incubated at 4 °C for 5 min at which time cell disruption was completed by ten strokes of a Dounce homogeniser. The nuclei were pelleted by centrifugation at 700g for 10 min, washed once with RSB buffer and then several times with RSB buffer containing 1% Nonidet P-40 and 0.5% sodium deoxycholate. The nuclear washes were pooled with the cytoplasmic fraction which was further clarified by centrifugation at 13,000g for 5 min. The nuclei were lysed by resuspension in buffer containing 0.01 M Tris-HCl (pH 7.4), 0.5 M NaCl, 0.006 M MgCl₂, 0.6 mM CaCl₂ and adjusted to 50 µg of RNase-free pancreatic DNase ml⁻¹. After incubation at room temperature for 20 min, EDTA was added to 0.01 M. Nuclear and cytoplasmic fractions were then incubated for 30 min at 37 °C in the presence of 0.5% SDS and 500 µg of Pronase B (self-digested) ml⁻¹. The preparations were adjusted to 0.05 M sodium acetate (pH 5.1), 0.01 M EDTA and 1% SDS, extracted three times at 56 °C with an equal volume of phenol saturated with 0.05 M sodium acetate (pH 5.1), 0.01 M EDTA, and precipitated twice with ethanol. Nucleic acids were pelleted at 13,000g for 30 min, resuspended in DNase buffer and digested with RNase-free DNase as described above. The samples were re-extracted with phenol-chloroform-isoamyl alcohol and precipitated with ethanol as described for the preparation of total cellular RNA.

Contamination of cytoplasmic fractions by nuclear RNA was less than 1% as determined by previously published procedures²⁸. As far as cytoplasmic contamination of nuclear RNA was concerned, no obvious cytoplasmic material was present in the nuclei preparations as determined by contrast-phase microscopy. Furthermore, nuclear RNA preparations contained less than 5% 18S ribosomal RNA which is indicative of cytoplasmic contamination²⁹. Hybridisation of nuclear and cytoplasmic RNA to cDNA_{src} was performed at 68 °C for 70 h as described in Fig. 1. Each point represents an average of three separate determinations. *a*, Cytoplasmic RNA; *b*, nuclear RNA. ○, RSV-transformed field vole clone 1; △, RSV-transformed field vole clone 22; ▲, revertant field vole subclone 4; ●, revertant field vole subclone 866.

RSV-transforming gene sequences since little or no difference in either the amount or the extent of transcription can be detected in these two cell types. Since the viral transforming gene sequences are potentially active in the revertant cell these data suggest that the control of the transformed phenotype in this cell system is under the influence of some post-transcriptional control mechanism(s). The fact that no differences in the amount of sarcoma-specific RNA found associated with polyribosomes could be detected between the transformed and revertant cell type further indicates that this post-transcriptional regulation does not involve either restriction of transport of sarcoma-specific RNA from the nucleus to the cytoplasm, or the lack of formation of sarcoma-specific polyribosomes in the revertant cell type. Although previous studies on other transformed-revertant cell systems have indicated that regulation of expression of the sarcoma gene sequences can occur at the transcriptional level⁹⁻¹², the data presented here is the first indication that the expression of this particular gene sequence

can also be regulated post-transcriptionally. Thus the mere presence of sarcoma virus-specific RNA in eukaryotic cells may not be sufficient to initiate transformation following infection of cells by RNA tumour viruses since the host cell must play an important part in determining which particular gene sequences are ultimately expressed. This may explain the situation that exists in normal avian cells which contain low levels of sarcoma-specific RNA but are by no means transformed (D. Spector, H. Varmus & J. M. Bishop, personal communication) and may reflect the requirement of a host cell component that the sarcoma gene product must interact with in order to establish and/or maintain transformation. It is conceivable that this host cell component is absent in subclones of revertant vole cells. These transformed and revertant field vole cells should therefore provide us with a eukaryotic cell system with which to study the transformed phenotype and the epigenetic host factors that are operative and required either to regulate or maintain the expression of the viral transforming gene functions. Experiments are currently in progress to determine if viral-specific proteins, including the sarcoma gene product, can be detected in the revertant subclones. Retransformation of the revertant field vole cells by RSV is also being attempted. Collectively these studies should contribute to our understanding of the level of restriction of sarcoma

Fig. 4 Detection and measurement of polyribosome-associated sarcoma-specific RNA in transformed and revertant vole cells. Total polyribosomal RNA from transformed and revertant vole cells was prepared essentially according to the method of Gielkins *et al.*³⁰. Briefly, cells were washed with phosphate-buffered saline containing 200 µg of cycloheximide ml⁻¹, resuspended in buffer containing 0.05 M Tris-HCl (pH 8.5), 0.225 M KCl, 0.008 M MgCl₂, 0.002 M dithiothreitol, 500 µg of heparin, 200 µg of cycloheximide ml⁻¹ and 2% Nonidet P-40 and disrupted with a Dounce homogeniser. Nuclei and cell debris were removed by centrifugation and the 13,000g post-nuclear supernatant was layered on to a discontinuous sucrose gradient. Polyribosomes were pelleted by centrifugation, resuspended in 0.1 M Tris-HCl (pH 9.0) containing 0.5% SDS, extracted three times with phenol-chloroform-isoamyl alcohol (50:50:1) and precipitated twice with ethanol. Polyribosomal RNA was then digested with RNase-free DNase, re-extracted with phenol-chloroform-isoamyl alcohol and precipitated with ethanol as described in Fig. 1. In control experiments, treatment of the polyribosomal pellets with 30 mM EDTA for 15 min at room temperature released 90% of the sarcoma-specific RNA sequences consistent with its function as mRNA. Hybridisation of polyribosome-associated RNA to cDNA_{src} was performed for 70 h at 68 °C as described in Fig. 2. Each point represents an average of two to four separate determinations. ○, RSV-transformed field vole clone 1; △, RSV-transformed field vole clone 22; ▲, revertant field vole subclone 4; ●, revertant field vole subclone 866.

gene expression in this cell system and ultimately, elucidation of the precise nature of the cell function involved.

We thank S. Kanellos and D. Nelson for excellent technical assistance and L. Honza for typing this manuscript. We also thank Dr H. Varmus for invaluable discussions and communication of data before publication, and Drs J. Yunis and L. de la Mazafir for providing us with the normal vole cell line. We are indebted to Dr J. Gruber and the office of Program Resources and Logistics, Viral Cancer Program, Division of Cancer Cause and Prevention, National Cancer Institute for supplying us with valuable reagents. This investigation was conducted under Contract NO1-CP-61055 within the Virus Cancer Program of the National Cancer Institute. R. K. and A. L. are currently postdoctoral fellows supported by NIH postdoctoral fellowship CA 05231 and training grant CA 09 138 from the National Cancer Institute, respectively.

Cis-trans isomerisation in rhodopsin occurs in picoseconds

It has been believed for some time that the primary event in vision, the photochemical formation of bathorhodopsin, can be attributed to a *cis-trans* photoisomerisation¹. Recently this model has been questioned. Busch *et al.* proposed that the less-than-6-ps formation time of bathorhodopsin from rhodopsin does not allow significant isomerisation of the 11-*cis* chromophore to an all-*trans* isomer². This apparent difficulty with the *cis-trans* photoisomerisation model has prompted alternative models including (1) a mechanism involving deprotonation of the Schiff base nitrogen³, (2) proton transfer from the retinal methyl at position

five to opsin^{4,5} (involving the shifting of double bonds along the polyene chain to form a 'retro' type retinal), and (3) a photoinduced electron transfer to retinal from a protein donor group⁶. We have approached this question by performing picosecond absorption kinetic measurements on the formation time of bathorhodopsin from bovine rhodopsin and isorhodopsin. The essence of this experiment is that bathorhodopsin, being the common photo-product of rhodopsin (11-*cis* retinal) and isorhodopsin (9-*cis* retinal) must be an isomerised product of at least one of these pigments, but could be a product of both pigments (that is, basically all-*trans* retinal). Thus formation time measurements of bathorhodopsin from the two primary pigments can settle whether isomerisation can take place on the picosecond time scale.

Rhodopsin is the visual pigment in disk membranes of vertebrate rod cells⁷. It is composed of the chromophore, 11-*cis* retinal, covalently linked through a protonated Schiff base to a small protein called opsin. On absorption of a photon by the chromophore, a consecutive series of thermal intermediates is formed ending in the release of all *trans* retinal and free opsin^{8,9}. The opsin binding site also accommodates a 9-*cis* retinal. This pigment, isorhodopsin, has the same thermal intermediates as rhodopsin. The first thermal intermediate, bathorhodopsin, has been shown to be generated from rhodopsin in less than 6 ps at room temperature and thermally decays in about 100 ns (ref. 2).

The picosecond apparatus is detailed in Fig. 1. Generated pump and probe pulses were at 530 and 561 nm respectively. Rod outer segment membrane fragments were isolated from dark-adapted bovine retinae essentially as described previously¹⁰. Solubilised rhodopsin was obtained by extracting the membrane fragments in 3% lauryldimethylamine oxide and 50 mM phosphate buffer (pH 6.6). Isorhodopsin was prepared photochemically¹¹ by taking some of the rhodopsin samples to liquid nitrogen temperature, irradiating using the 568.2-nm krypton laser light, and warming. All measurements were taken at room temperature, and the sample stirred between each laser pulse to avoid light induced sample changes in the laser light path. No average sample degradation was observed during the experiments as measured by standard ultraviolet-visible absorption spectroscopy.

In these measurements, care must be taken so as not to over drive the sample in the laser beam during the picosecond pulse. For example, significant amounts of isorhodopsin can be produced from a rhodopsin sample at high light levels. Calculations using an average intensity for the laser pulse, the quantum yields^{12,13} and absorption constants at the pump wavelength show that less than 10% of the rhodopsin sample in the laser path would be converted to isorhodopsin and similarly for isorhodopsin to rhodopsin. Also, for the pump intensities used, the yield of bathorhodopsin starting with isorhodopsin would be about half the yield of bathorhodopsin from rhodopsin, in agreement with the experimental results.

The time dependence of the laser-induced absorbance changes for the conversion of rhodopsin and isorhodopsin to bathorhodopsin are shown in Fig. 2. The salient feature of the curves is the rapid rise within 9 ps. Thus, the photochemical formation of bathorhodopsin from either rhodopsin or isorhodopsin occurs in less than 9 ps. The time to reach half the limiting absorbance change¹⁴ is about 3 ps. This is an indication of the formation time of bathorhodopsin. The formation time from rhodopsin is in agreement with the work of Busch *et al.*².

As briefly argued above, bathorhodopsin must be an isomerised product of at least one of the primary pigments. Proof for this is given by recent resonance Raman work (a technique sensitive to conformation¹⁵). Similarities between the resonance Raman spectra of the 11-*cis* protonated Schiff base in solution and rhodopsin, and between the 9-*cis* protonated Schiff base and isorhodopsin, show that the conformations of the retinals of rhodopsin and isorhodopsin are 11-*cis* and 9-*cis* respectively, and are not particularly distorted by the surrounding protein^{16,17}. In addition, the resonance Raman spectrum of photochemically produced isorhodopsin¹¹ is identical to that of regenerated 9-*cis* retinal¹⁸ and opsin, proving that complete photoisomerisation(s) about two double bonds takes place in the rhodopsin → bathorhodopsin → isorhodopsin phototransitions. Either at the

ing telescope lens system, a time delayed reflection echelon (14 steps at 4.5 ps per step), filters F_3 and F_4 to eliminate 530 nm, a focusing lens on sample 1.06 μm and 530 nm pulses are 9 ps and 7 ps respectively.

Fig. 1 Schematic representation of the experimental system. The components include: a Nd^{3+} glass oscillator with cavity mirrors M and saturable dye absorber; a single pulse selector consisting of two crossed polarisers, Pockels cell and spark gap; a half wave plate and 'clean-up' saturable dye absorber; two Nd^{3+} glass amplifiers (gain $\times 20$); filter F_1 to eliminate flash lamp; a second harmonic generator; filter F_2 to eliminate 1.06 μm ; a 15-cm benzene cell to produce stimulated Raman scattering at 561 nm; specially coated mirrors to separate the 530 nm and 561 nm beam paths; in the 561 nm path, an expand-

first or the second photoreaction or at both photoreactions a major isomerisation must take place. Thus, there is no doubt that bathorhodopsin, being a common photoproduct of both rhodopsin and isorhodopsin, is an isomerised product of at least one of the primary pigments.

Our picosecond results show that major photo-induced isomerisation(s) of retinal in bovine rhodopsin can take place on a picosecond time scale since both rhodopsin \rightarrow bathorhodopsin and isorhodopsin \rightarrow bathorhodopsin photoreactions take place in less than 9 ps. In agreement with our observations, Warshel¹⁹ has shown that picosecond isomerisation times are theoretically feasible in rhodopsin, although this theoretical approach relies heavily on the exact nature of the excited state potential surfaces which are difficult to obtain precisely.

Huppert *et al.*⁹ have performed kinetic measurements with protonated retinal Schiff bases in solution, and report nanosecond recovery kinetics which are ascribed to isomerisation times. From our results and theirs, it seems likely that in the visual pigments the photoisomerisation times are greatly accelerated by chromophore-protein interactions. That the protein significantly

modifies this retinal property is not surprising. In contrast to retinals in the visual pigments, protonated retinal Schiff bases in solution have blue-shifted absorption bands and much reduced, wavelength dependent quantum yields of photoisomerisation¹³.

Finally, our results do not describe the exact nature of bathorhodopsin. Rosenfeld *et al.*¹³, however, using the basic early arguments of Hubbard and Kropf¹ and Yoshizawa and Wald²⁰ concerning the properties of bathorhodopsin (or lumirhodopsin), recent resonance Raman data¹⁵, and recent artificial pigment work have recently argued that the chromophore of bathorhodopsin must have essentially a *trans* conformation but not necessarily a planar one. Our results remove any uncertainty from these arguments due to the picosecond isomerisation times.

We thank Professor Honig for useful discussions, and Princeton Applied Research for the use of an OMA. This work was supported in part by US NSF grants (P C M 75 13155A01 and BMS 75-03020) and grants from City University Research Award Programs and Philips Laboratories. B.H.G. is a Philips Fellow and R.R.A. an Alfred P. Sloan Fellow.

Fig. 2 Laser-induced absorbance changes at 561 nm as a function of time in detergent solubilised bovine rhodopsin (\times) and isorhodopsin (\bullet) at room temperature. Bathorhodopsin is the only intermediate during the bleaching of bovine rhodopsin known to absorb strongly at 561 nm. The energy of the 530-nm pump pulse was about 10^{-4} J; the energy of the 561-nm probe pulse was about 10^{-7} J. The beam sizes were about 1 mm² for the pump and 0.5 mm² for the probe. The samples (about 1.5 ml) were held in 0.5-cm cuvettes. The concentrations were about 4 A cm^{-1} at the absorption peaks near 500 nm; the ratios $A_{400}:A_{500}$ were about 0.3; and ratios $A_{530}:A_{500}$ were about 0.7 for rhodopsin and 0.5 for isorhodopsin. Each data point shown is the average of six (rhodopsin) and nine (isorhodopsin) laser shots. Typical mean standard deviations are ± 0.03 . The zero time is located using a 0.5 cm CS_2 Kerr optical shutter²¹ at the sample site. The half width at half maximum for the CS_2 shutter prompt response curve is about 6 ps.

reviews

Darwin's papers

Frederick Burkhardt

The Collected Papers of Charles Darwin. (2 Volumes.) Edited by Paul H. Barrett, with a Foreword by Theodosius Dobzhansky. Pp. viii+277+326. (University of Chicago: Chicago and London, 1977.) £27.30; \$40 the set.

THESE volumes bring together 152 papers which Darwin published over a period of forty-seven years. They range in length from a paragraph to forty-eight pages. Thirty-three of them first appeared in *Nature*, between 1869 and 1882. Others were contributions to learned societies of which Darwin was a member: the Geological (12), Linnean (9), Zoological (4), Geographical (1), and the Royal (1). (His sole contribution to the Royal Society was his solution of the problem of the 'Parallel Roads of Glen Roy', a paper he later called a 'gigantic blunder'.)

The largest number of items (50) are from *The Gardeners' Chronicle and Agricultural Gazette*, the medium Darwin used for communication with plant and animal breeders. The rest of the papers are mainly from periodicals concerned with popular but serious discussion of scientific matters, like the *Natural History Review*.

An appendix lists fifty-two articles dealing with the species collected by Darwin on the *Beagle* voyage, in itself a considerable bibliographical contribution. All of Darwin's notes are preserved. Professor Barrett's notes are relatively few in number and are concerned with identifying persons and places and explaining technical terms.

The effect produced by the papers in their totality is dramatic in the way they make clear the range of Darwin's interests, his powers of observation, his imaginative questioning, his probing for facts that he hoped would corroborate his hypotheses, and his astonishing talent for experimentation.

The papers naturally vary considerably in scientific and historical significance. Some are famous, like the joint paper with Wallace in which Natural Selection was first announced, and his remarkable papers on plant physiology.

Some of the brief and apparently ephemeral items are now seen to be important in Darwin's work on his species theory. As Theodosius Dobzhansky points out in his appreciative and graceful Foreword, Darwin's short query about 'A Mouse-Coloured Breed

of Ponies' was really asking 'Have the species horse and ass descended from a common ancestor?'. Similarly, Darwin's experiments on the ability of seeds to survive immersion in salt water were designed to provide him with an explanation of the geographical distribution of species that could dispense with creationism and Forbes's vast continental extensions.

Although this is primarily a reference work, there is plenty of interesting and readable material in it. Darwin wrote many of the pieces in clear non-technical prose for those interested in such subjects as erratic boulders, the fine dust that falls on ships in the Atlantic, mimetic butterflies, the fertilisation of British orchids, the origin of certain instincts, or the biographical sketch of an infant.

Scholars will want to know how complete the collection is. The answer depends on what criteria are used in selection. Professor Barrett includes only papers published by Darwin in his lifetime. Richard Freeman, in his new edition of the bibliographical handlist of Darwin's works includes posthumous articles, memorials, and items privately printed and circulated by Darwin. On

Professor Barrett's criteria, each work has four items overlooked by the other. Using Mr Freeman's standards, but omitting repetitive printings, nine more might have been included. For example, Darwin's important 'Queries about the Breeding of Animals' is omitted by Barrett because it was printed and distributed privately, but the 'Queries about Expression' is included because it found its way into an Annual Report of the Smithsonian Institution. Again, Professor Barrett omits three items because the books to which they were contributed were published after Darwin's death. Since these circumstances in no way affect the authenticity of the writings or their importance, it seems arbitrary to deny them a place in a *Collected Papers*.

This editorial question aside, Professor Barrett deserves great credit for making these writings available in a convenient and reliable collection in which scholars and non-specialists alike will find both profit and pleasure.

Frederick Burkhardt, President Emeritus of the American Council of Learned Societies, is co-editor, with Sydney Smith, of the prospective Collected Letters of Charles Darwin.

Complex systems

The Foundations of Cybernetics. By F. H. George. Pp. xiv+286. (Gordon and Breach: London, Paris and New York, 1977.) £13.50.

THE last page of this book contains the following comment "... about the word Cybernetics. In America it is now slightly frowned upon, and although the word is currently more acceptable in the United Kingdom it is still suspect in some quarters. . . . The problem stems from the arbitrary divisions we have in our sciences, and the very slow conservative attitude of scientists towards the development of scientific ideas and classifications. . . ."

Up to a point the complaint deserves sympathy. Much can be gained from interdisciplinary work. There is, of course, little to stop the individual from drawing his own "arbitrary divisions". Whether his new subject becomes acceptable to the larger community depends on what it has to offer and the following it can attract.

Broadly, Cybernetics encompasses the study of complex systems. On the one hand there are the man-made systems of automation and computer technology and, on the other, those provided by nature, such as the brain of man and other physiological organs. There is, one hopes, a conceptual framework common to both. The man-made systems can serve as a source of analogies for the development of theory in psychology and physiology while, in the reverse direction, the living world can act as a source of inspiration to inventors.

The book is concerned with the, as yet undeveloped and unconnected, conceptual framework that may serve the two sides. There are chapters on feedback, finite automata, neural nets, logic, computers, information theory, and aspects of psychology and physiology. With a net cast so wide, it is not surprising to find that the treatment of some topics is superficial. This means that for information on any one

of the topics one could do better by turning to more specialised sources. As a book of its kind, however, it is one of the best.

It is clear from the evidence presented that Cybernetics still awaits its breakthroughs. As a body of theory it has little to offer and seems to have taken almost everything it has from other disciplines. The developments envisaged by Wiener, Ashby, and others, that can result from the interaction of ideas from biology and technology do, of course, continue to take

place; but, perhaps not, as they had hoped, under the heading of Cybernetics. Ironically, there is the consolation that the "arbitrary divisions" which, some thirty years ago, marked out this new field of science are not likely to become hard-set, and thereby to obstruct future changes in the internal boundaries of science.

V. Zakian

V. Zakian is Lecturer at the University of Manchester Institute of Science and Technology, Manchester, UK.

Heterocyclic chemistry

Stereochemistry of Heterocyclic Compounds. Part 2: Oxygen, Sulfur, Mixed N,O, and S, and Phosphorus Heterocycles. By W. L. F. Armarego. Pp. xviii + 494. (Wiley-Interscience: London and New York, 1977.) £32.65; \$54.

ALTHOUGH the literature of organic chemistry includes many comprehensive surveys of the stereochemistry and conformational analysis of carbocyclic compounds, scant attention has hitherto been given to the corresponding aspects of heterocyclic chemistry. Numerous discussions of isolated topics in this vast, comparatively neglected area are scattered throughout the review literature, but the present two-volume set appears to be the first monograph to attempt a review of this field as a whole. This second volume is devoted to the stereochemistry of oxygen, sulphur, mixed nitrogen, oxygen and sulphur heterocycles, and a final chapter deals with phosphorus heterocycles.

The organisation of the volume is the same as that of the first, even to the extent that the first brief, introductory chapter, which explains the order of discussion of the data, is identical in the two volumes. Each section begins with a discussion of the stereochemical aspects of the synthesis of compounds in the group, then follows a discussion of the configuration, and then the conformation, of the compounds, and finally stereochemical aspects of their reactions are discussed. The whole project is one of daunting proportions; this is amply illustrated by the fact that this second volume alone contains a bibliography of over 2,400 references, which cover the subject completely up to the end of 1974, and incompletely for 1975. Presumably because of the enormous volume of material to be reviewed, the final chapter has been contributed by M. J. Gallagher.

The coverage of this material in under 450 pages of text has resulted in inevitable restrictions; the style is of

necessity compressed, but it is clear, critical, and very readable. Where earlier authoritative reviews exist, the author has been concerned primarily with updating them. Important stereochemical principles and illustrations of syntheses and reactions are taken mainly from the behaviour of model compounds, and a discussion of the vast number of natural products is not attempted. In the present context this includes, for example, furanose and pyranose carbohydrates, penicillins and cephalosporins. Steroidal epoxides are also among the groups omitted; however, in all these areas, the excellent bibliography provides a ready entry into these aspects of the subject, as well as providing a comprehensive bibliography for readers who wish to pursue the subject matter of the text in greater depth.

The book is beautifully produced, and typographical errors are rare. The formulae have been very skilfully drawn by the author's talented amanuensis, the heteroatoms and substituent groups being inserted manually rather than in the usual type-face. This has presumably resulted in some economy in production, and it has also obviated one possible source of errors, without any sacrifice of production standards. There is a moderately detailed subject index, which also includes the names of authors mentioned in the text; there is no separate, complete, author index.

This volume certainly fills a very important gap in the review literature of heterocyclic chemistry, and since, with its companion volume on nitrogen heterocycles, it heralds the introduction of a new series of monographs on general heterocyclic chemistry, each volume in which will survey one aspect of the whole field of heterocyclic chemistry, it is to be particularly welcomed. It will be immensely useful to advanced undergraduates and to research workers in heterocyclic chemistry, and it surely belongs in every chemistry library and heterocyclic research laboratory.

Biological tools

Introduction to the Spectroscopy of Biological Polymers. Edited by D. W. Jones. Pp. xii + 328. (Academic: London and New York, 1977.) £11.60; \$25.50.

SPECTROSCOPIC techniques have played no less an important part in the structural studies of biological macromolecules than they have in more classical studies of simpler molecules, and the range of spectroscopies, if differing in emphasis, has been equally as wide. Consequently, an author or editor aiming to produce a book that covers all or most of the spectroscopic techniques used in studying biological polymers sets himself an unenviable task. He not only attempts a synthesis of several highly specialised subjects but does so, unlike his many predecessors who have undertaken similar enterprises in a purely chemical context, knowing he can make very few assumptions about his readers' knowledge of mathematics and physics.

The editor of this work has overcome the problem of the multidisciplinary nature of his subject by choosing an author eminent in each field to contribute a chapter on that speciality. He has sandwiched these chapters between a general introduction to molecular spectroscopy and a concluding chapter briefly describing some examples that illustrate the power of combining several spectroscopic techniques to tackle a specific biological problem. The approach throughout is descriptive and not mathematical, and several difficult physical concepts are explained clearly.

The most original aspect of the book is the strong emphasis placed on the use of vibrational spectroscopy. The chapter on Raman spectroscopy is particularly welcome as advances in laser technology over the past decade have made this technique a powerful biological tool. No less welcome and more surprising are the two chapters on infrared spectroscopy. They illustrate the potential of this technique especially when combined with Fourier-transform analysis. They also link the work done on biological polymers with that done on the industrially important synthetic polymers. The remaining chapters cover absorption, emission, optical rotation, circular dichroism, nuclear magnetic resonance, electron spin resonance and Mössbauer spectroscopy.

M. T. Flanagan, until recently a member of the Biophysics Division of the National Institute of Medical Research, London, is now with Standard Telecommunication Laboratories, Harlow, UK.

Space-time proceedings

Asymptotic Structure of Space-Time. Edited by F. Paul Esposito and Louis Witten. Pp. vii+442. (Plenum: London and New York, 1977.) \$51.

In recent years it has increasingly become the practice for the proceedings of international scientific conferences to be published a year or so later in a single volume at an exorbitant price. Occasionally these collected works are very useful as a comprehensive review of a new or rapidly developing subject, and if well written and edited can provide students with a convenient access to up-to-date work. All too often, however, the proceedings are a hotchpotch of incomplete articles, bearing only a superficial connection to each other, and coexisting under the same cover merely to avoid offending some of the conference contributors.

The usefulness of conference proceedings is still further reduced when preprints of the papers are thoroughly circulated beforehand and all the publisher does is to bind together reproductions of these manuscripts (often containing barely legible hand-written mathematical symbols and a multiplicity of type faces) and offer the end-product for anything up to a few dozen dollars.

Many of these volumes are now being offered to university libraries labouring under stringent budget controls, so that would-be purchasers are becoming much more discerning in their requirements. They will be interested to know that *Asymptotic Structure of Space-Time* is, by these recent standards, very well put together. True, the price, at \$51, is regrettably high, but most of the manuscripts have been well prepared and typed, and the papers are of a fairly uniform style and standard. The conference took place in Cincinnati in June 1976, and covers a selection of important and fast-moving new developments in mathematical relativity and space-time structure. After a useful and well written introduction by R. Geroch the reader is treated to a discourse on cone space, (Brian Bramson), conformal bundle boundaries (B. G. Schmidt) and complex vacuum metrics (J. F. Plebanski and I. Robinson). I was disappointed that the theory of twistors did not receive some prominence, but there are two good papers on the related topic of H-space (E. T. Newman, K. P. Tod and M. Ko), although these are far too condensed.

The recent resurgence of interest in quantum aspects of gravitation is reflected in a (once again, too short)

paper on supersymmetry by P. van Nieuwenhuizen, together with an excellent and very readable review on quantum field theory in curved space and particle production by gravitational fields, by Leonard Parker. I found this one of the best presented of all the papers, and its list of 168 references is a masterpiece of literature research.

My overall impression of this book is that it is well edited and presented, and is nice to have available.

Paul Davies

Paul Davies is Lecturer in Mathematics at King's College, University of London, UK.

Methylmercury intoxication

Minamata Disease: Methylmercury Poisoning in Minamata and Niigata, Japan. Edited by T. Tsubaki and K. Irukayama. Pp. 310. (Kodansha: Tokyo; Elsevier: Amsterdam, New York and Oxford, 1977.) \$48.25; Dfl. 118.

METHYLMERCURY intoxication is now frequently called Minamata disease as it was first around the Minamata Bay that methylmercury caused a mass epidemic. One of the best parts of the book deals with the background and epidemiology of this and a similar epidemic in Niigata. The Minamata epidemic started in 1941 with individual cases and its epidemic proportion was noticed in 1956 when it was first believed to be of infectious origin. In 1958 Dr McAlpine, who saw some of the patients, called attention to the similarity between Minamata Disease and methylmercury intoxication. His paper written with Dr Araki and published in the *Lancet* in 1958, but not mentioned in the otherwise detailed historical and clinical account, turned the attention to mercury; and subsequently methylmercury was identified in sediments, seafood and in the drainage system of the Minamata factory.

Although the number of yearly cases declined, new cases were reported as late as 1972-73, which is not surprising as the mercury concentration in shellfish remained up to that period of about 5 p.p.m., but sometimes as high as 16 p.p.m. The situation was not very different in Niigata, where the ban on fishing in the Agano river did not prevent new outbreaks, which are discussed in this book as intoxications with delayed onset. Whether methylmercury is able to precipitate disease long after the cessation of exposure is an important problem, but inadequately handled in the whole book. There is also a certain reluctance to re-value past views: data based on the dithizone

method is interpreted without reservation although according to a table this method, compared with atomic absorption, generally underestimated tissue mercury levels by a factor of 3.

Translation is very uneven and often puzzling. A sentence like "After an interval of 14 years, one of the 4 cases came to necropsy, and was found to be grossly ataxic; blindness of the left eye and severe constriction of the visual field in the right eye persisted" is more than a puzzle, but it might illustrate the difficulty of interpreting some paragraphs with less blatant error. It might be that the translation is responsible for the surprising statement that mercury half-time in the brain was calculated from autopsy material.

Despite shortcomings, *Minamata Disease* is an important publication on the origin, epidemiology, pathology and clinical aspects of the two outbreaks in Japan. It would be a very much better book, however, if publications of this type were submitted to the same rules as any publication in a learned journal: revision based on the suggestions and criticisms of two referees.

Functional groups

Chemistry of Functional Groups. Supplement A: Chemistry of Double-Bonded Functional Groups. Parts 1 and 2. Edited by S. Patai. Pp. 651 each part. (Wiley: London, New York, Sydney and Toronto, 1977.) Part 1 £29; \$52.50; Part 2 £29.50; \$55. Suppl. as a set £58.50; \$107.50.

SUPPLEMENT A to *Chemistry of Functional Groups* is the first in a set of planned supplementary volumes to this well established series. The aim of the Editor is to include in them the "missing chapters" from earlier volumes in addition to providing other chapters to extend and bring up to date the material in the earlier volumes. The two parts of this supplement A relate chiefly to earlier volumes in the series on alkenes (1964 and 1970), the carbonyl group (1966), the carbon-nitrogen double bond (1970), and the azo group (1975).

The first part contains chapters in which all of the above groups are considered, usually separately within each chapter. Reviews on dipole moments, configurations and conformations of molecules, liquid crystals, and thermochemistry provide a timely reminder of the value of an understanding of the physical properties and structures of organic molecules as a basis for a study of their reactions and reactivity. The chapters which follow on the mechanisms of elimination and addition reactions, electrochemistry, 1,3-dipolar cycloadditions, and the reactions of carbenes, demonstrate the rapid developments in these areas in recent years, and provide the reader with a clear picture of the advances that have taken place.

Part two commences with a review on the formation of unsaturated groups by heterolytic fragmentation. It is particularly useful in showing that numerous apparently different reactions conform to a common pattern of reactivity and lead to the formation of compounds with double-bonded functional groups. The remaining chapters are on more specific subjects, and are concerned with reviews of electrophilic additions to carbon-carbon double bonds, the olefin metathesis reaction, oxidation of $-C=C-$ and $-C=N$ groups, and transition metal-catalysed carbonylation of olefins, imidines and diamides (1,3,5-triazapentadienes).

All chapters in the supplement are of the nature of essay reviews not claiming to give encyclopaedic coverage. They are well written with clear diagrams and reaction schemes. Although

coverage is selective, the authors have been careful to choose illustrative examples that demonstrate the essential principles they wish to convey. Cross references are given to earlier volumes in the series as well as to other reviews and to many individual papers. In some chapters as many as 500 references are provided.

The main value of this series is that a reader on studying a particular chapter will get a clear overall picture of the aspect of chemistry that it covers, and will be able to explore more deeply by consulting the references provided. In this supplement, the chapters vary in the ground they attempt to cover; some survey enormous fields, others bring together reactions of a number of different functional groups within a coherent framework, and yet others cover very specific topics. Within the framework of the

series these two volumes represent valuable additions to their parent volumes published earlier. They will be useful to undergraduate and postgraduate students, and also to research workers in industry. The scope of the series makes its price beyond the pockets of individuals but these volumes, like the others in the series, will be most important additions to the libraries of teaching and research establishments specialising in organic chemistry. The series is likely to increase in value particularly when, in these inflationary days, the range of review journals and periodical reviews subscribed to by libraries have to be curtailed on financial grounds.

Water and tropical agriculture

Climate, Water and Agriculture in the Tropics. By I. J. Jackson. Pp. xii+248. (Longman: London and New York; 1977.) £3.75.

SINCE temperature is always adequate for plant growth in the tropics, the main climatological limitation to agriculture is often inadequate rainfall. *Climate, Water and Agriculture in the Tropics* by Jackson therefore covers what is potentially an important field. The author has spent six years lecturing in Tanzania, so he has first-hand experience of the problems and is well qualified to write this particular book. He examines the characteristics of tropical rainfall and evaporation, together with their implications, especially as related to agriculture, land use and other aspects such as soil erosion and irrigation. Early chapters consider the origins of tropical precipitation, rainfall seasonality and variability, and rainfall intensity. The general atmospheric circulation of the tropics is discussed briefly. Only one chapter is devoted to evaporation, with a short discussion of methods of estimation. The final chapters are concerned with water-plant relationships and the book ends with a discussion of man's impact on the hydrological cycle.

The tropics are vast in area, and cover a great variety of climatic types. It is therefore impossible in a book of limited length to cover all aspects of tropical plant-water relationships. Although the coverage of the book is

wide, it does tend to concentrate on the humid tropics of Africa and Asia, with particular emphasis on the statistical aspects of rainfall. Considering its importance to the energy balance of tropical plants, evaporation is discussed somewhat briefly. Evaporation depends largely on the available radiation, but there is no discussion of the distribution of solar radiation in the tropical world. Given an adequate water supply, plant yields depend to some degree on the available solar radiation, which in the summer hemisphere can increase away from the equator, leading to the highest crop yields in the subtropics. This is another reason for introducing some discussion on tropical solar radiation patterns. Considering that the book is essentially about water and tropical agriculture, it is a pity that there is not a really substantial section on the problems of drought and desertification in the tropics. Both problems have assumed some importance in recent years, especially as there are suggestions that there is a feedback mechanism between desert formation by overgrazing, and decreasing rainfall.

The main strength of this book lies in its discussion of tropical precipitation; here it fills a gap in the available literature on this subject. The book is well produced and well illustrated, and includes an extensive list of references. It should prove invaluable to specialists concerned with tropical water resources, and also provide useful reading for students of the agriculture, climatology or geography of the tropics.

Destination without route-map

NOSTALGIA, as more than one wag has said, is not what it used to be. Nor, according to Denis Hayes, is the future. The entire world, he argues in his Worldwatch Institute book *Rays of Hope* (published this week in the United States*), stands at the edge of an "awesome discontinuity" in its production and use of energy—hence the book's subtitle, 'The transition to a post-petroleum world'. In trying to anticipate what that world could look like, it is undoubtedly an important sketch of a growingly complex picture; its flaw, if that is what it is, is that it ignores how the disputed views of the final canvas are to be reconciled and implemented.

Firmly in the now well-established tradition of Worldwatch publications, the lucidly written and remarkably broad-ranging exposition is a valuable synthesis of existing work, here in the burgeoning field of energy—indeed, it is a synthesis of a synthesis, incorporating Hayes' already-published arguments on conservation, nuclear power and solar energy. Designed also to influence as well as inform, it has a clear message to convey: the three energy sources on which to build a self-sustaining post-petroleum world, namely coal, nuclear and solar, have narrowed to just one—the sun; the technology is already available, now is the time to move.

Part of the argument is familiar enough. The fossil fuels outlook is discouraging: without a change, the current generation will consume most of the oil and gas. Resource, environmental and climatic constraints make coal just a transitional fuel. The nuclear outlook is even less encouraging: the threats of proliferation and terrorism come on top of problems of radiation, waste, uranium resources, breeders and safety. With fusion's promise weak, that leaves the safe sustainable sources—the sun, wind, water and 'plant power'—and a crying need for conservation.

To see it simply as a 'pro-solar' or as an 'anti-nuclear' book would be a mistake, however, though it is this almost to a fault and as convincing as anything that has taken the opposite point of view. The book's relentless onslaught on the wasteful use of energy, specifically in food production, transport and construction, together with its detailed technical picture of a more energy-efficient world is especially welcome. So too is its historical and global perspective, although parts

are plainly pitched to a US audience.

Where the argument is different, but also troubled, is in the character of its advocacy. Worldwatch's president, Lester Brown, says in a foreword that the question is not whether or not we make the transition, but whether it will be smooth or chaotic. Unfortunately Hayes seems to believe it is better to arrive than to travel, for he is as short and unenlightening on how politically to secure his alternative as he is long and rewarding on what, in energy terms, the world ought to look like under it.

On a subject this controversial, this is a rather glaring omission. To consider global energy problems without considering the global political economy is like scaling a mountain without allowing for the weather. But few books go even as far as Hayes does. It also remains unfortunately true that people let the unpredictability of the weather mask their appreciation of mountains, and he has undoubtedly taken account of this. Yet in a book whose underlying theme is world-wide change, questions are bound to go begging when the technical changes are teased out while the concomitant social changes are not. And that is exactly what happens.

We are told—but only told—of the 'weighty' depletion issue, which focuses on the discount rates that the markets and the politicians apply to, say, a future barrel of oil. We are told of the highly centralised technocratic and authoritarian societies that nuclear power fosters. We are also told that there is neither a 'quick fix' nor a *deus ex machina*, that the coming transition is unlikely to be smooth and painless, that there will be opposition. And we are told that the issues are not scientific and technical, but social, political and philosophical—that redistributions of land and of wealth must be enormous, both within and between countries.

This too will demand some authoritarian action, for, historically speaking, a more explosive political issue is difficult to find. But for Hayes it must be the subject of another book. So we are left with rays of hope instead of straws, and an argument for a least bad option. It is a pity. Perhaps, as he intimates, civilised societies must discover their own solutions and carve out their own paths. But in an interdependent and competitive world, events look more and more like intervening to do their own damage. This book was needed five years ago. Even with it, people will regret not being institutionally prepared as well as technically competent to survive the impending threat of holocaust.

*Denis Hayes, *Rays of Hope: The Transition to a Post-Petroleum World* (W. W. Norton, September 1977) \$3.95

A good time to raise standards

EVERY year we scan the statistics of The Universities Central Council on Admission (UCCA) for trends, and occasionally we get rapped over the knuckles for misinterpretation. This year's figures, just out, offer the usual happy hunting ground.

The statistics, as always a year late, refer to those who applied during the year 1975-76, generally for entry in October 1976. They show applications up again to around 142,000. Overseas candidates, particularly from the Commonwealth, continue to grow in number more rapidly than home candidates—in 1976 they accounted for one in seven of all applicants. Places were found for 74,000 applicants; the figure for total applicants, which is always about twice the number accepted, includes a large number who subsequently fail to gain adequate school qualifications, who withdraw, who are applying for the second time and so on. So it must not be inferred that there is a genuine shortage of places.

Engineering continues its run of popularity (which started well before the recent governmental campaign). Projections to 1977 suggest there are now at least 40% more applying for engineering than in 1972. And even mathematics, physics and chemistry—which lost popularity until 1975—may now be sharing again in the general rise in applications.

Simple head-counting, however, conceals some striking variations in quality. The relative paucity of candidates in mathematics, physics and chemistry does not seem to have led to a diminished standard in those accepted—at least as far as paper qualifications go. Indeed the school performances of accepted physicists rival those of accepted medical students—the latter a category in which universities can be very selective. Good scientists still seem to be coming forward. The position is somewhat different in engineering. Rising quality has not gone along with rising numbers, which may mean that schools have been urging more of their modestly accomplished pupils to consider engineering.

It is against this background that one must consider the suggestion made in the report that universities may soon have to allocate further resources to alleviate the 'critical situation' which seems to be developing in engineering places. Only two or three years ago, of course, we were being told by the engineers of half-empty departments: it is hard to believe the turn-around has been that dramatic. But maybe the universities, rather than create more spaces, should become more selective as time goes on, in the hope of creating a genuine impression amongst students not just that the country welcomes engineers, but that standards in engineering are high. □

Research funding: the new trichotomy

William S. Hillman comments on the relevance of the dichotomy of 'pure' and 'applied' science

THE dichotomy contrasting 'basic' and 'applied' research is still commonplace in discussions on funding. Such discussions often conclude that one mode is over-supported at the expense of the other. Yet on most reasonable definitions of the two, history suggests that neither prospers alone. The old dichotomy is at best misleading, and distracts attention from a more immediately dangerous aspect of current policies. That aspect invites analysis by trichotomy, if you will excuse such language.

Strictly speaking, nothing in the current situation is entirely new. Reasonably enough, the patrons of science have always wanted useful results, quickly if possible. But the main dispenser of patronage now is government, with its self-justifying administrative hierarchies, and it has finally become clear that the taxpayers' resources are finite. In addition, occasional spectacular successes, such as moon landings, have been inappropriately but invidiously contrasted with (for example) the 'failure' of NIH research to abolish cancer. Recent versions of the king's desire for the alchemists' gold have thus split research into at least three recognisable types: real, imitation (or administrative) and defensive. The terms are not quite self-explanatory, but they correspond roughly to real gold, fool's gold and the elusive quicksilver.

Real research is originated, organised and carried out by investigators who understand the field in question. It is aimed at problems which in the view of those investigators are both important and reasonably likely to reward the effort with some return in understanding, control or both. The 'applied/basic' dichotomy is meaningless here. A salient characteristic of real research is that it engages the best judgment of capable scientists. The subjective elements in this description (who is 'capable'?) do not obscure the distinction between it and the second category.

Imitation research, in contrast, starts with the belief that, because science has proved useful in the past, scientists should be able to do anything, right now, given the funds, proper organisation and (most important) what sports writers call desire. This is all regardless of whether the necessary concepts, techniques and people actually exist. The primary motive for organising imitation research is neither controlling nor understanding nature, but pleasing one's superiors. That those superiors should know little about the opportunities and limitations in specialised fields is inevitable, but many organisers of imitation research either share that ignorance or are simply cynical. Hence manifold reports, detailed timetables and complex flow charts are prominent features of the game, leading naturally to the synonym 'administrative research'. The overriding rule is that the players must avoid being corrupted by luxuries such as intellectual rigour, imagination and patience; to that end, frequent exercises in relevance, interdisciplinary communications modalities and urgency are scheduled.

What, finally, is defensive research? The notion is analogous to that of defensive driving in that both recognise the hazards of assuming people will behave sensibly; or to the developing style of defensive medicine, in which procedures that are legal safeguards for the physician may be wasteful for both the patient and society. Defensive research, in short, is what so many scientists must do who would prefer to be doing real research but lack private incomes. The result is that a core of real research becomes surrounded with a set of possibly quite worthless elements designed to impress those who want the gaudy imitation rather than await the real thing.

There is no space here for examples, but few readers will need them. Very likely some policy-makers, here and there, in one agency or another, will indignantly deny any knowledge of imitation or defensive research. But they are easily answered with a paraphrase of the ancient epitaph: if you need examples, look around you. □

From détente to development

Eric Burhop reports on the discussion between scientists at the 27th Pugwash Conference

ATTEENDANCE at the 27th Pugwash Conference, held in Munich on 24–29 August, was as always on an individual basis, facilitating the frank and uninhibited exchanges between scientists of very different backgrounds that has always been a feature of Pugwash. Two hundred and sixty participants from 54 countries met to discuss problems of universal concern: détente, human rights, energy and development. About 50 of them came from countries of the Third World. Those not attending on an individual basis included 18 observers representing governmental international organizations.

In his address to the opening session, Herr Matthöfer, Minister of Research and Technology of the Federal German Republic, remarked "Today Pugwash is a very familiar name, indeed a symbol of the responsible active efforts of scientists from all over the world to help solve the major world-wide tasks of humanity across political and ideological barriers".

For those who may not be so familiar with the history, Pugwash is the name of a small Nova Scotian village, birthplace of the Cleveland, Ohio, industrial magnate, Cyrus Eaton, who financed the first of these conferences held there in July 1957. The call for the holding of such a conference came in a remarkable statement drafted by Bertrand Russell in his incomparably clear and compelling language and beginning: "In the tragic situation which confronts humanity, we feel that scientists should assemble in conference to discuss the perils that have arisen as

a result of the development of weapons of mass destruction . . .". *The statement goes on to spell out to the world the grave and immediate dangers to the whole of humanity implicit in the development of the hydrogen bomb. It was signed by Einstein only two days before his death in May 1955 and by nine other eminent scientists from six countries. The Russell–Einstein Manifesto, as it has come to be known, was presented to the world at a press conference presided over by Joseph Rotblat and held in Caxton Hall, London, in July 1955.

Two roles

There have always been two conceptions of the aims of the Pugwash Conferences. The Russell–Einstein Manifesto looked to them to rouse public opinion to the dangers of the development of nuclear weapons by issuing statements which, coming from scientists of such eminence and integrity, could be ignored neither by peoples nor by governments. The other concept of the role of Pugwash as providing facilities for private discussions between the very experts from NATO and Warsaw Pact countries who were advising their governments on problems of weapons development and disarmament, was especially associated with the thinking of Leo Szilard.

Both Pugwash roles have had an important effect on relations between the two power blocs in the past. The mutual understanding of each other's thinking has made remote the possibility of stumbling into nuclear war by accident, through, for example, wrong interpretation of observations on a radar screen. Pugwash Conferences have been credited with playing a significant role in achieving the Partial Test Ban and Non-Proliferation Treaties and in the development of the theory of deterrence with its strange array of concepts such as first and second strike capability, mutually assured destruction and all the rest.

The general conferences are held

every year, the participants from each country or region being selected by local Pugwash groups. Every fifth year the whole Pugwash community, made up of every participant in previous Pugwash meetings, is eligible to attend. This quinquennial conference elects the principal officers and council of approximately 25 persons that will direct the work for the following five years, assesses the work of the previous quinquennium and plans the future programme. The Munich Conference was a quinquennial one, indeed the largest yet held.

Customarily the conferences work mainly through working groups which deal with specific topics, preparing reports for plenary sessions in the concluding stages of the conference. At the Munich Conference there were eight such groups dealing with nuclear arms control and disarmament; arms control and disarmament in the non-nuclear realm; coexistence, détente and cooperation between nations and systems; security of developing nations; development problems of the economically poor nations; energy, world resources and population trends; environmental hazards of global concern; science, scientists and society.

The prevailing judgment of the first working group was that the SALT talks are not progressing fast enough to prevent advances in military technology which negate the effect of agreements, based on SALT, already reached. The time for stopping the arms race is running out. There were powerful pleas to examine again basic concepts such as that of deterrence which can at best provide a breathing space. Pugwash should take the lead in pressing for a start on real disarmament and not restrict its approach to arms control measures.

Almost unanimous concern was expressed by several groups about President Carter's decision to go ahead with the development of the neutron bomb. The idea of a weapon specifically designed to kill people while preserving property largely intact has caused a wave of revulsion and it was suggested that Pugwash could recapture some of its old sense of urgency in an appeal to public opinion on issues such as this and on the reported development of a nuclear capability by South Africa.

Public statement

It is the practice of Pugwash that its conferences, symposia, workshops, etc, issue reports of discussions and recommendations for the benefit of Pugwash members but public statements formulating specific policies on such matters can come only from Council. (See box for the statement issued by Council on these questions,

Eric Burhop is Professor of Physics at University College, London, and President of the World Federation of Scientific Workers.

Russell at the 1955 press conference

**It is not widely known that originally Russell was himself sceptical about calling a conference. He envisaged simply the issuing of a statement. The proposal to add the call to scientists to meet in conference was made by Frédéric Joliot-Curie on behalf of the World Federation of Scientific Workers, of which he was President, in a letter to Russell in January 1955. The writer acted as go-between in the negotiations between Russell and Joliot-Curie.*

reflecting the discussions at the Munich Pugwash Conference.)

The discussions on détente predictably led on to problems of human rights in an atmosphere largely free of acrimonious interchange of charge and countercharge. Appalling departures from acceptable standards are reported from many countries while no country seems faultless. However, the approach to human rights problems should be guided by how to help the victims. They have been used all too often for propaganda purposes or even to attempt to destabilise governments. Discussions on human rights issues tend to be simplistic, the fact that human rights cannot be separated from human responsibilities being forgotten. Nor can the question be adequately discussed in isolation from its social and political framework.

The question of energy supplies practically dominated the discussions on world resources. There was general agreement that ultimately energy needs must be met from solar, wind, geothermal and safe nuclear fusion power but no consensus about how we are to get through the next 40 or 50 years. There was some but not much enthusiasm for the fast breeder solution and a feeling that there was still some time available before committing us to a full programme of fast breeder reactor development. If a determined programme of energy saving were coupled with control of population growth, one could realistically aim for

a situation in which, by the year 2020, the world population would not rise above 6.7×10^9 with an average energy use of 5 kWt (kilowatts-thermal)—8.0 kWt (rich nations), 3.2 kWt (poor nations)—within a global rate of energy use of only four times that of today. It is believed such a level of demand could be met without introducing breeder technology.

North-South divisions

The problems of development loomed large in the conference discussions. Indeed, any differences in the conference were far more between North and South than between socialist and non-socialist countries. Many delegates from the Third World do indeed feel that their problems are inadequately dealt with by Pugwash and stress that problems arising from the policies of the industrialised countries relative to the Third World, the role of multinational companies, and also to a lesser extent contradictions between Third World countries themselves may represent the most serious threat to peace. On the other hand, some participants looked back somewhat nostalgically to the early Pugwash Conferences when participants were all more or less expert in some aspect of the field of nuclear weapons and it was possible to issue sharp, incisive statements in this field, carrying great weight. A few felt that there would be a case for two separate types of Pugwash Conferences, one specifically de-

voted to disarmament and the other to Third World problems. This would surely be a retrograde step and could only sharpen North-South divisions and the overwhelming view was in favour of continuing as at present.

Pugwash has developed a certain mystique and influence of its own. Some may think it elitist and self-perpetuating; some may chafe at the confidentiality of the discussions, which is an essential feature of the whole Pugwash concept, but it seems that Pugwash is a powerful force for peace and understanding between nations. Thanks to a band of devoted scientists, too numerous to mention but from whom at the present time could be singled out Joseph Rotblat, Bernard Feld, Martin Kaplan, Moishe Markov and Dorothy Hodgkin, the ideas of Russell and Einstein have remained alive and the Pugwash movement has become a living movement with its members showing a genuine sense of loyalty to these ideas and of belonging to the movement.

Of the tasks ahead special emphasis should be placed on the participation of Pugwash in two vital UN meetings; the Special Session of the UN General Assembly on Disarmament in the spring of 1978, and the UN Conference on Science and Technology for Development in the summer of 1979. In both these areas the world community has grievously failed in the past. Here is perhaps an opportunity for a new beginning. □

Declaration by the Pugwash Council

In the light of discussions at the 27th Pugwash Conference on Science and World Affairs, the Council of the Pugwash Movement feels impelled to issue the following declaration:

The world is poised for a new, more intensive and more dangerous round of the arms race. Three features of the world scene account for our sense of heightened urgency and danger:

New weapons of mass destruction. The neutron bomb is proposed for development in the heart of Europe. It is sometimes called a 'clean' or damage-free bomb. On the contrary, both its lethal radiation effects and the short and long-term biological damage it would cause are substantially greater than for existing nuclear weapons of comparable size. There would be strong induced radioactivity from neutron capture in the soil. Because of its relatively small size, it would narrow the distinction between conventional and nuclear weapons and thereby make the use of nuclear weapons more likely.

But the neutron bomb is only one example of new types of weapons now coming into military arsenals: cruise missiles, mobile ballistic missiles, and

others. These are often provocative and thus destabilising. Their deployment is not verifiable with national means, and thus frustrate efforts at control. And the number of nuclear warheads continues to mount. *The deployment of all these new weapons must be stopped.*

Proliferation. There was serious concern at the conference over reports of an imminent nuclear-weapons test in South Africa. This concern was not allayed by the assurances by the South African Government that it has no intention to do so. The acquisition of nuclear weapons by South Africa would be a grave peril to the peoples of Southern Africa and the rest of the world. Developments there must be kept under intense continuing surveillance. Any collaboration with South Africa in the nuclear weapon field—whether on the governmental, commercial or scientific level—must stop. The United Nations should be urged to apply effective sanctions should South Africa be proven to be developing nuclear weapons.

But South Africa represents only the most urgent and immediate occasion for concern. At various points around the globe there have been, from time to time, disturbing reports of states seeking

nuclear weapons. We unequivocally condemn moves towards further nuclear weapon proliferation.

The failure of arms control. In spite of endless efforts, progress towards limiting armaments and stopping the arms race has been all but invisible. Everywhere there is a new sense of impasse. And this is particularly ominous in the SALT and MBFR negotiations. There is no military reason for their failure to make progress. No nation's security would be endangered, indeed it would be enhanced, by much lower levels of armaments. The obstacles are political and it requires only political will and political decisions to overcome them.

● We call on the heads of concerned governments and states all over the world, particularly of the USA and USSR, to halt new weapons deployment and reverse the arms race.

● We call on men and women everywhere to redouble their efforts to make their governments understand and act in the face of our common peril.

And we in Pugwash rededicate ourselves to the achievement of a world at peace.

GEOS

Salvaged results

Stuart Sharrock reports on some of the preliminary results from experiments aboard Geos

At a champagne breakfast on 20 April at Cape Canaveral, European Space Agency officials were gloomy. Instead of celebrating the successful launch of the Geos satellite they were contemplating the total failure of the whole mission. But within a few days the Geos ground control at Darmstadt had partially rescued the situation—although not in the planned geostationary orbit, the satellite would at least be spending some time in the right place.

This would have been a hollow victory, however, if it had meant no scientific results, so the experimenters had to retrieve what they could. In Munich last week they met to discuss their preliminary findings. Although there are some problems, remarkably, there are already some interesting results. After only four months it is clear that much of the scientific programme is going to be a success. But the role of Geos as the reference spacecraft of the International Magnetospheric Study (IMS) cannot be restored and the success of the experiments makes it imperative that the second spacecraft should be launched into geostationary orbit in the near future.

Geos was planned as the first geostationary satellite devoted solely to magnetospheric research. It followed

the ATS series of satellites which confirmed that a geostationary orbit was ideal for studying the magnetosphere. The intention was to launch Geos 1 into geostationary orbit early in 1977; the second identical satellite, Geos 2, was to be launched into an elliptical geosynchronous orbit in December 1979 by Ariane, ESA's own launch vehicle now under development. The second mission, codenamed Geosari, was to be complementary to the first, providing a wider spatial coverage of the magnetosphere. The only changes to the second payload would be improvements to the experiments found necessary as a result of experience gained during the first Geos mission.

The attractiveness of Geos as a tool for investigating the magnetosphere is based on the uniqueness of its planned orbit and the sophistication of its payload. Its position was planned to lie on magnetic field lines connecting northern and southern auroral zones. In addition, its geostationary orbit would have allowed average conditions to be established, deviations from the average indicating temporal rather than spatial variations. As the near-earth environment is not static this discrimination is important, but it can only be fully achieved by simultaneous use of more than one satellite such as the pair of satellites of the ISEE mission due for launch in October.

Although Geos has lost these advantages because it is not in geostationary orbit the possibilities opened up by the comprehensive nature of the experiment package still largely apply. It is still possible during part of Geos' new orbit to make simultaneous measurements on waves and particles whilst monitoring the background electric and magnetic fields and plasma density.

When the malfunctioning Delta launch vehicle failed to place Geos into the correct transfer orbit it was clear that injection into a geostationary orbit was not possible. ESA's Space Operations Centre at Darmstadt however managed to place it into a 12 h elliptic orbit with an apogee of around 7 earth radii using the apogee boost motor (see diagram). The orbit was chosen because the satellite is visible around apogee for about 10 hours per day from the ground receiving station near Darmstadt.

Initially the local time of the apogee of the orbit was in the evening sector, but it gets progressively earlier, drifting at a rate of 1 hour every 17.5 days. It has just passed the earth-sun line and

will start to move into the night sector around Christmas. The aurora are much more active in the night sector and so any correlated measurements with rocket campaigns will have to wait until 1978.

So far each experiment has been operated independently and there are still a few interference problems to be sorted out before the optimum mode of automatic operation of the experimental package will be known. But the initial data indicate that the Geos payload is sophisticated enough to provide reliable measurements of electric fields and plasma densities outside the plasmasphere. All data obtained so far are from the afternoon sector of the magnetosphere.

In perhaps the most ambitious experiment on board, an electron beam is fired from the satellite perpendicular to the local magnetic field (determined by another Geos experiment). It is deflected by the geomagnetic field in a circular path of several kilometres radius to return to the satellite close to its source. The distance between the source and the point of return depends on the electric field and the gradient of the magnetic field; the two contributions can be sorted out by varying the energy of the emitted electrons and the plasma drift velocity and direction can be determined. This is difficult to verify on earth as a vacuum chamber a few kilometres long would be required in a magnetic field of less than 100 γ . Unfortunately after about one week of operation the oxide cathode of the electron gun became poisoned but, even with only a few days data, the viability of the method was proved.

Another experiment measuring electric fields—in line with the Geos philosophy of providing redundant measurements of important parameters—has also been successful and interesting slow fluctuations have been seen which have yet to be correlated with data from the ULF wave experiment. The electrostatic wave experiment has been able to detect electrostatic waves with the help of information on the plasma frequency provided by an exploratory experiment using the first relaxation sounder to be launched above the ionosphere.

A variety of electromagnetic wave

Geos orbits: planned and achieved

phenomena have been observed, and some have been related with measurements at ground stations. It will be interesting to correlate these results with those from the various particle experiments but there are still some problems. Confusion over the number density and temperature of the plasma, however, may well be resolved by a determination of the energy spectrum of the various particles, but it needs further investigation of the contribution of the observed photoelectron cloud from the satellite itself and of the effects of spacecraft changing. These problems may be solved later in the year when Geos goes into eclipse.

Some experimenters have been unable so far to completely understand their results through the lack of reliable attitude data necessary to sort out spin modulation effects. But it should be only a matter of time before the relevant analysis programs are fully working.

The experiments measuring high energy particles are least affected by these problems. Preliminary results from a sophisticated mass spectrometer for measuring ion composition, indicate the presence of the doubly charged ions $^4\text{He}^{++}$ and $^{16}\text{O}^{++}$ deep in

the magnetosphere. The new orbit of Geos is almost a bonus in this case because ion compositions can be measured as a function of distance from the earth. Another unexpected bonus of the new orbit is the fact that Geos now spends considerable time near the geostationary satellite ATS-6. Earlier attempts to persuade NASA to drift ATS-6 past the planned geostationary position of Geos were unsuccessful but now the possibility of correlated measurements with similar instruments on the two satellites has become a reality.

The progress that has been made in such a short time after the disappointment of the failed launch is impressive and prospects for the future look bright. But most of the Geos programme in which coordinated measurements were planned with ground-based campaigns has had to be abandoned. Indeed the rocket campaigns from northern Sweden have been persistently plagued with bad luck. The rockets are supposed to pass through the transient auroral arcs and correlate their measurements with satellites poised at magnetically conjugate points above the equator. On the first launch ATS-6 was in position but the rocket exploded.

Geos should have been in position for the second rocket but delays had pushed back the Geos launch date and it was still on the ground. ATS-6 had meanwhile moved on. These difficulties are increased by the refusal of Norway to allow the rockets to overfly their territory and the consequently restricted rocket range makes it very difficult to hit the aurora. There are two rockets planned for 1978 and the rocket team hope their luck will change and that the second Geos spacecraft will have been launched into geostationary orbit.

Geos 2 has already been refurbished and will be of flight standard by the end of the year. It can either be launched into geostationary orbit by NASA early in 1978 using another Delta launcher, or it could wait until late 1979 to be sent up on ESA's own launcher Ariane. An early reflight on a Delta is what the experimenters want—from the way they have evaluated their data in such a short time they have in a sense earned it—and from some view points this appears the most likely option, but the extra cost to ESA will be about \$14 million and it is unclear where this will come from. ESA is expected to decide early in October. □

USA

Opening a biological pathway

The signing of the Panama Canal Treaty last week has implications for the ecology of the Atlantic and Pacific Oceans. Colin Norman reports

AMID the diplomatic fanfare and loud political protest which greeted the signing last week of the Panama Canal Treaty, muted rumblings of a scientific controversy were also faintly audible. The controversy centres on a little-noticed article in the Treaty committing the United States and Panama to conduct a joint study of the feasibility of building a sea-level canal within a few miles of the existing waterway.

The idea of carving out a direct, sea-level link between the Pacific and Atlantic Oceans has been investigated many times in the past, but political, economic and technical problems have so far kept it from becoming a reality. In fact, in spite of the renewed official interest in the idea, it is still considered unlikely that the channel will ever be dug. Nevertheless, the possibility is worrying some marine scientists, who fear that a sea-level canal would damage the ecology of the surrounding oceans.

The worry stems from the fact that

the tropical Pacific and Atlantic Oceans have been separated for perhaps five million years, since North and South America were joined by the isthmus or Panama. Consequently, marine life has evolved independently in the two oceans for long enough to ensure that few species are common to both. Blasting a sea-level link across Panama would open a biological pathway which may result in the migration of plants and animals into a new environment, a process which some marine scientists believe could have considerable impact on the oceans' ecology.

Very little migration takes place through the present canal because a freshwater lake in the middle of the waterway provides a barrier to most marine life, and the large number of locks along the canal means that there is little flow of water through the system. A sea-level canal would, however, be an entirely different prospect. Tidal ebb and flow through the canal, coupled with the fact that the average sea level on the Pacific side is slightly higher than that on the Atlantic side, could result in the transport of plants, animals, larvae and other organisms through the channel.

Among the more dramatic consequences that have been predicted as

a result of breaching the land barrier are the possibility that the yellow-bellied sea snake, a poisonous reptile which now lives only in the Pacific water, could become established in the Caribbean, and that the crown-of-thorns starfish might similarly invade the tropical Atlantic coral reefs. Other potential worries are that fish travelling through the canal might carry pathogens or viruses which are not known to native species. The central problem in such interchange is that the introduction of flora or fauna into a new environment might upset the ecological balance because there may be no natural predators and native species may not have evolved an effective defence mechanism against the newcomers.

Such possibilities are, of course, highly speculative, and some marine biologists contend that it is very unlikely that major environmental damage would result from opening a sea level channel. Nevertheless, there are several sobering examples of previous experience with the introduction of animals and plants into a new environment. For example, the building of a canal to bypass the Niagara Falls, providing a channel joining the Great Lakes to the Atlantic, has resulted in invasion of the lakes by a predatory fish-like creature called the sea lamprey. The lamprey has spread throughout the Great Lakes,

and decimated native species. Similarly, the introduction of the European rabbit into Australia and New Zealand was followed by a population explosion which caused serious damage to vegetation and topsoil.

Such concerns were given wide publicity in the late 1960s, when the sea-level canal last came under serious study. A Presidential Commission, established in 1964, conducted a major feasibility study of such a canal, examining potential routes, engineering problems and the possibility of using nuclear explosives to blast out a channel. In 1970, the Commission recommended that the project should go ahead, along a route about 10 miles west of the present canal. Excavation should be by conventional means, the Commission said, and it calculated that the effort would cost about \$2,900 million in 1970 dollars.

Because of the high price tag, and in view of political problems in re-negotiating the existing Panama Canal Treaty, the Commission's recommendations were never implemented, and the whole idea swiftly dropped out of the limelight. It is, in fact, something of a surprise that the idea has been resurrected in the new canal treaty.

As part of the Commission's study, the National Academy of Sciences and the Battelle Memorial Institute were asked to conduct independent analyses of the likely ecological impact of opening a sea-level link between the Pacific and the Atlantic. The Academy's report, which was published as an appendix to the Official Commission Report, must rank as one of the most forthright statements of concern ever to emerge from that august institution. Calling the sea level canal "a gigantic natural experiment" which will have "unforseeable" consequences, the Academy called for a massive study of the tropical Pacific and Atlantic ecosystems before the project is allowed to go ahead. "Available information is altogether insufficient to allow reliable predictions of particular events resulting from the excavation of a sea-level canal in Panama", the Academy said.

The Battelle report was, however, more sanguine about the impact, noting that although there is scant knowledge of the ecology of the region, there is "no firm evidence to support the prediction of massive migrations from one ocean to another, followed by the extinction of thousands of species". The Commission itself was even less impressed with the warnings of disaster. It devoted a mere four pages of its report to a discussion of environmental concerns and concluded that the hazards, whatever they may be, would be "acceptable".

The argument for building a sea-level

Miraflores locks, preventing flow between Atlantic and Pacific

waterway is simply that the present canal is already heavily travelled and it is likely to reach its capacity in the 1990s. Moreover, its locks are too small to take the large freighters and supertankers which are now appearing on the oceans. Such limits were, in fact, realised, back in the 1930s, when work was begun on the construction of a series of larger locks alongside the present canal, but construction was stopped during the war and it was never resumed. (The new Panama Canal Treaty in fact calls for a study of the feasibility of completing the construction of the old locks as an alternative to building a new sea-level canal.)

More recently, a new argument has appeared: a sea-level canal will be needed to transport Alaskan oil and gas to the east coast of the United States. According to this argument, which has been advanced most prominently by Senator Mike Gravel of Alaska, the cost of building a new canal (about \$5,900 million at today's prices, Gravel reckons), should be measured against the cost of building a new pipeline system to transport Alaskan oil and gas from the oil-rich west coast to markets in the east. Once all the advantages are counted up, Gravel reckons that the canal will seem like a bargain. He has stated that he will seek congressional approval for the 1970 report to be up-

dated.

In anticipation of such renewed interest, Dr Frank Press, President Carter's Science Adviser last month asked the National Academy of Sciences to take a fresh look at its earlier report to the Commission to see whether recent scientific data are available to help predict more precisely the likely environmental consequences. Last week, the Academy Committee held two days of hearings and it is hoping to produce a report for Press by early October. Judging from last week's meeting, the Committee is likely to conclude that although a good deal of work has been done, knowledge of the Panamanian ecology is still too sparse to predict with certainty the impact of breaching the land barrier between the tropical Pacific and Atlantic oceans.

Asked last week when the joint US-Panama study envisaged in the treaty is expected to get under way, a State Department spokesman said that no details have yet been worked out. The first priority will be to steer the treaty itself through conservative shoals in the Senate. In view of the immense political problems involved in re-negotiating the treaty, the prospects for negotiating a new treaty to build a sea-level canal in Panama must, at this point, be considered remote. □

USSR

● Training enough highly qualified scientific manpower is a major problem of the Soviet economy. According to the current five-year plan, some 9.6 million new engineers, technologists, agronomists, doctors and other specialists will enter the labour pool by 1980, with increasing emphasis on graduates in molecular biology, environmental protection, atomic and electronic technology, electrical instrumentation, automation, agriculture and forestry. To train them the Soviet Union now has 859 universities and other higher educational institutions, and 4,303 technical colleges. The problem is not simply one of training, however; the proper deployment of scientific personnel is a constant topic of discussion.

Current planning policy calls for closer integration of research in industry. One way to bring this about is to involve university students in projects with an immediate industrial application. Speaking at the opening of the new Grodno State University last month, S. M. Carnau, Minister of Education of the Byelorussian SSR, noted with approval the "widespread attraction of students of senior courses" towards choosing as their term or diploma project a specific contract for research from an industrial enterprise or organisation. This, he said, has considerably extended the "geography" of application of young scientists' talents.

One potential source of close association between academic life and industrial needs would seem to be through the considerable numbers of external and evening students. In the present academic year, the 'full-time' university and technical college intake is estimated by *Pravda* as "more than a million". If the demand for new scientific personnel during 1981-85 equals or exceeds the 9.6 million of the current five-year plan (as all available figures indicate), and assuming a current annual university intake of 1.2 million, by the early 1980s almost one-third of the new graduates will come from external and evening courses.

Unfortunately, these 'part-time' graduates do not necessarily return to industry. The current 'press discussion' of the new Draft Constitution recently included a long letter from a certain Senior Engineer A. Akimova from Khabarovsk, suggesting that 'part-time' graduates should be compelled, by law, to return to their former 'collective'. Ms Akimova complains that in spite of the self-sacrifice of their fellow-workers, who

have to cover their duties when they are absent on paid leave taking examinations, and who "try to provide the conditions of study" during work breaks, many young graduates "on receiving the diploma of a specialist, straight away try to find a

more advantageous job". Ms Akimova's letter, like the majority of contributions to the 'debate', takes the form of a shop-floor proposal, but also like the majority of such letters, has wider implications than the complaint of a few disgruntled workers. It would clearly be to the advantage of the managers of industrial enterprises if they could be sure that the promising young workers involved in part-time education would remain at the disposal of their own production team after graduation, instead of disappearing into the general scientific labour pool.

● This year marks the fortieth anniversary of the first 'North Pole' drifting ice-floe station, in which a five-man team drifted for 274 days in the vicinity of the Pole. That expedition established a valuable research procedure which still continues; this summer 'North Pole' 22 and 23 continued the tradition.

In comparison with these long-term voyages, the recent dash to the Pole by the 'Arktika' icebreaker appears to have had only a limited role in gathering meteorological, geophysical and oceanological data. The expedition was clearly considerably prestigious, and its heroes will doubtless figure prominently in the forthcoming 60th Anniversary Celebrations of the October Revolution. But all in all, only 15 h were spent at the Pole, which included time spent in ceremonial flag-hoisting, rocket-firing and holding hands round the pole.

The main scientific value of the voyage would appear to relate to the design and performance of the

'Arktika' herself. According to A. I. Fokin, Deputy Minister of the Shipbuilding Industry, 100 scientific research institutions were involved in the design of the ship and equipment. A new navigational procedure was tested—the use of helicopters instead of the traditional crows'-nest lookout, to locate the best route through the ice. It is claimed that as a result, speed increased 50-100% and the 'Arktika' reached the Pole seven days ahead of schedule, even though the floes were at times 4 m thick. A new and even more modern icebreaker, the 'Sibir', whose cabins will have independent suspension, obviating the effect of hull motion, will be completed shortly.

The northern sea route, between European Russia and the Soviet Far East is of considerable importance to Soviet economic planning. Commenting on the success of the 'Arktika', Timofei Guzenko, the leader of the expedition and Minister of Merchant Marine remarked that the commercial use of the route is now a "real possibility". The immediate problem, he said, is to build ships capable of following the icebreakers through the paths they have cleared.

Meanwhile, the world's first research icebreaker, the 'Academician Otto Schmidt' is being built in Leningrad for the Institute of Arctic and Antarctic Research. The vessel will carry fourteen laboratories for oceanological, meteorological, hydrological, and ice research, a special unit for aqualung divers and a computer for the on-board processing of research results.

● Using 'Pisces-7' and 'Pisces-11' self-propelled diving craft, a limnological expedition has succeeded in reaching the bottom of Lake Baikal, the biggest and deepest rift-trench in Asia. According to Evgenii Mirlin, leader of the expedition, the main purpose was to apply the techniques developed for ocean-bed research to a study of the lake bed. The programme includes underwater photography of geological formations, and a study of the unique flora and fauna of the lake. Even at the greatest depths, said Mirlin, shrimps, Baikal bullheads, and the small semitransparent *Comphorus baicalensis* can be found.

The team spoke highly of the 'Pisces' craft, which, in addition to providing facilities for visual observations and still and TV photography, have special mechanical arms for collecting geological samples and specimens of water.

Vera Rich

IN BRIEF

A voice for geologists

Geologists in Britain who have felt for some time that they should have a collective voice for the profession have just founded an Institution of Geologists. The institution will aim to advance the profession and practice of geology by 'shaping opinion' in various centres of power and taking an interest in matters of professional standards, education, remuneration and so on. There are about 4,000 geologists in Britain, and a quarter of them have taken an interest in the founding of the institution.

The Geological Society of London, which will provide premises for the institution, was unable to perform these functions itself by virtue of being a learned society with charitable status. But in the long run many hope that the two bodies will operate jointly.

New line of questioning

The case of the dissident Moscow mathematician, Anatolii Shcharanskii, who has been held incommunicado since his arrest last March has now taken an ominous turn; last week, his fellow refusenik Vladimir Lazaris was called to the Lefortovo prison to answer questions about Shcharanskii's mental stability. Although Moscow activists feel it is too early to assess the significance of this new line of questioning, they feel that its proximity to the International Psychiatric Congress in Honolulu, at which the Soviet Union was censured for its use of psychiatric means of political repression, should not be ignored.

CFC policy

The UK government's policy not to ban the use of chlorofluorocarbons

(CFCs) in aerosols until much more research has been undertaken, is supported in a statement issued last week by the Clean Air Council, a statutory body set up to advise the Secretary of State for the Environment on air pollution. The Clean Air Council regards as tenuous the argument that CFCs lead to depletion of the ozone layer in the atmosphere allowing increased ultraviolet radiation to reach earth and possibly cause damage to health (for example, skin cancer).

Since measurements began in the 1920s, the amount of ozone has in fact increased by 5-10%. The statement points out that 'natural' variations are enormously greater than those so far calculated to be a result of the use of CFCs. While supporting further research on CFCs, the Council regards the moves in the USA to ban their use as "precipitate".

THE World Health Organisation (WHO) is rightly concerned with nutrition, and with the more efficient production and distribution of the earth's resources. WHO has fortunately stopped putting forward absurd statements, such as the one that more than half the world's population is starving, which damaged its earlier reputation. The situation in many countries is serious enough without dramatic exaggerations. Some millions of people die annually of starvation, and several hundreds of millions are underfed for at least a part of the year.

Yet there is no need for this suffering. The world produces more than enough for every member of its population to receive an adequate and healthy diet. If waste and greed could be abolished, there would already be enough to feed the extra three or four thousand million mouths expected by the year 2,000. People starve, or are underfed, because they are poor, and cannot compete in the world market with the consumers in rich countries. The most voracious and wasteful of these consumers are livestock, the battery hens, pigs in sweat houses and barley beef, which waste both calories and protein to add to the pleasure of western palates.

The richer countries also have nutritional problems, but these arise from over and not under eating. When we hear that one of our friends is 'on a diet' we immediately understand that he is trying to lose weight gained by previous over-indulgence. Slimming is becoming big business. A substantial part of the food processing industry is making

allegedly non-fattening products. Newspapers fill their columns with bizarre diets which are often so revolting that their victims will lose weight. Health farms charge over-fed

Cuisine minceur

KENNETH MELLANBY

pop stars more than five star hotels for organised starvation. Even reputable scientists explain how we may try to mislead our stomachs into believing that they have been generously indulged on a minimum number of calories.

A sophisticated attempt at making the best of both worlds—of gluttony and abstinence—is made by Michel Guérard in his new *Cuisine minceur* roughly translated as 'Slimming cookery'. The author runs one of the best, and most expensive, restaurants

in France. His book claims to be "an authoritative and authentic guide to a revolutionary new method which is sweeping the world of haute cuisine". It contains some good recipes; I was glad to learn how to produce a delicious *purée-mousse d'artichauts* and use up the glut of globe artichokes, one of the few vegetables spared by the plague of rabbits in my Huntingdonshire garden. But the new method seems mainly to eschew the more calorific dishes, and to use sugar substitute and *crème fraîche*, a tiresome preparation containing buttermilk. In fact in her introduction, Shirley Conran gives the game away, pointing out that M. Guérard's portions are small, for "if you eat large quantities of food, no matter what it is, you are not going to lose weight". Surely it would be sensible to avoid all this bother, and eat even smaller amounts of normal recipes. M. Guérard's dishes taste even better when made with real cream.

Clearly we should make the best of both worlds. If we in the West ate less we should be healthier, and there would be enough for the underfed nations; surely mankind is not too stupid to be unable to solve the economic difficulties. But we must learn that the only cure for over-eating is abstinence, not a fancy diet. Few are as naïve as the plump girl I heard lamenting her inability to eat enough starch-reduced bread, but the view that some foods encourage thinness is still widely held. High-protein diets are only slimming because they are so expensive. We should remember that the only sweetmeat with a truly non-fattening centre is the polo mint.

correspondence

Roots of 'enzyme'

SIR,—There can be no doubt that Kühne introduced the word *Enzym*, from which, of course, was formed its English equivalent. The reasons for his choice are discussed in at least two printed sources^{1,2}. But the actual construction of the word from Greek originals is less certain, in spite of some very definite statements in the literature.

Bayliss gave a translation of the relevant passage of reference 2, in two slightly different versions in *The Nature of Enzyme Action*, page 11–12 (Longmans, London 1925) and *Principles of General Physiology* (Longmans, London). The words concerned in the former are as follows " . . . but it merely states that *εν ζυμη* [in yeast] something occurs that exerts this or that activity, which is considered to belong to the class called fermentative". Nothing could be clearer: rarely do we have as precise knowledge as this of the thought processes of an author. However, Greek words do not occur in the original at all. They are an interpolation by the translator, whose immense authority and influence has led to almost universal acceptance of this version. The original runs at this point, " . . . sondern nur gesagt, dass in der Zyme etwas vorkomme, das diese oder jene zu den fermentativen gerechnete Wirkung habe . . .".

Bayliss's translation of this passage is, in other respects also, remarkably inaccurate. But unless there is concrete evidence of Kühne's intentions we are reduced to considering probabilities, and this direct construction from *εν ζυμη* still seems rather more likely than the alternative etymology put forward in *The Oxford English Dictionary*. According to this authority, the word was formed on modern Greek *ενζυμος*, meaning 'leavened', or more specifically the leavened bread used in the Eucharist of the Greek Orthodox Church. The very word 'enzyme' was used in English in 1850 in this sense. It seems unlikely that Kühne would have had any knowledge of modern Greek and, if not, this derivation appears to be impossible, even though it preserves a connection with the primitive meaning of the word 'ferment' which Kühne was seeking to replace.

As pointed out by Plantefol, in

Comptes Rendus de l'Académie des Sciences **226C**, 1976, a compound had already been formed in Greek meaning 'yeast in' rather than 'in yeast', so that Kühne's probable sequence of thought was somewhat unfortunate. But even Plantefol seems unaware of Bayliss's blunder. Plantefol also quite justly comments that 'enzyme' has merely taken over the functions of the pre-existing word 'diastase'. (In neither case is the etymology of any relevance to modern ideas of the nature and function of the substances concerned). It seems regrettable, if irretrievable, that this usurpation should have occurred.

Yours faithfully,

Proton-electron mass ratio

SIR,—Sirag (28 July, page 294) states that the proton-electron mass ratio is 1836.109, and derives a combinatorial prediction of 1836 for this quantity. The most recent editions of the *Review of Particle Properties* give 1836.1514 ± 0.0073 , some 21 standard deviations away. While the accepted value for the proton mass has changed significantly since about 1973, the value 1836 for the ratio m_p/m_e has been getting less and less plausible for at least the past 15 years.

The value $6\pi^3 = 1836.1181$ has been calculated, on very different grounds, to be this mass ratio (see *Physics Today*, page 17–19, August, 1971, for discussion). It is substantially closer to the most recent experimental value, but is still in disagreement by 4.6 standard deviations. It is also perhaps worth drawing attention to the apparent tendency of stable hadrons (and the muon) to have masses which are integral multiples of $3m_e$, the threefold electron mass. This has been discussed by R. Frosch in *Lett. Nuovo Cim.* **8**, 633 (1973), and at a meeting of the

Swiss Physical Society, Geneva, 8–9 October, 1976.

Was Darwin the Bellman

SIR,—The uncanny resemblance of F. Waddy's engraving of Darwin on the cover of 21 July to Henry Holliday's picture of the Bellman in the 1876 edition of *The Hunting of the Snark* by Lewis Carroll (Macmillan) (see below) and the 1962 edition of *The Annotated Snark* by Martin Gardner (Penguin Books), must have caused many to suspect that Darwin was the Bellman. This suspicion is confirmed by the two tufts (of hair?) at the foot of Waddy's picture, strongly suggesting that Darwin, in

"Supporting each man on the top of the tide

By a finger entwined in his hair"
had inadvertently scalped two of the crew.

Was it really the Snark that the Bellman was after in his voyages in H.M.S. Beagle (see pp28–31 and p52 footnote 17 in *The Annotated Snark*)?

Yours faithfully,

Ultraviolet observation of a quasar spectrum

from B. E. J. Pagel

QUASARS of high redshift permit emission and absorption lines of the far ultraviolet region to be observed from the ground. But what would the spectrum of a quasar look like if it could be observed over a really wide range of (rest) wavelength, say from 0.09 to $1\ \mu\text{m}$? At first sight one might think that this question can be answered by putting together the spectra of several quasars spanning the full range of observed redshifts, and indeed a good deal of useful work has been done along these lines leading in particular to the discovery that the Lyman- α emission line of hydrogen is not much stronger than the red H α line although straightforward theories predict that it should be about an order of magnitude stronger. However, there are severe difficulties in piecing together the spectra of quasars with different redshifts because of the wide range in their intrinsic properties: thus (if one makes the most plausible assumption, that the redshifts are 'cosmological', that is, symptomatic of great distances) the quasars that are actually observed generally become intrinsically more luminous at the higher redshifts, their brightnesses are subject to uncertain cosmological corrections and they are seen through increasing amounts of intervening material in intergalactic space and possibly in clusters of galaxies and even in galaxies themselves.

Consequently it has been clear for some time that observations of the ultraviolet spectra of quasars would help to answer crucial questions concerning both the nature of quasars and the distribution of diffuse matter in the Universe. Furthermore, if 'standard candles' can somehow be identified among quasars, then there is the possibility of using the enormous distances to which they can be seen to obtain really decisive results in

cosmology. But quasars are faint (the brightest one by far being 3C 273 with apparent magnitude 13 and redshift 0.16) and have been beyond the range of past experiments with rockets and ultraviolet satellites, so that the first results were expected to come from the next generation of space observatories using large reflectors, particularly the IUE (to be launched at the end of this year) and the NASA Space Telescope (planned for 1983).

Some of the exciting results awaited from the next generation of space telescopes have now been anticipated, however, in a remarkable rocket experiment carried out by members of the Physics Department of Johns Hopkins University (Davidsen, Hartig and Fastie, this issue of *Nature*, page 203), in which a Faint Object Telescope (FOT) of 40 cm diameter (the largest ever to be flown in a sounding rocket) with a concave grating giving a resolving power of about 150 was used to observe the spectrum of 3C 273 between 1,080 and 1,465 Å in its rest frame.

Despite the limited resolution, Davidsen *et al.* have been able to draw a number of interesting conclusions from their spectrum of 3C 273. It shows Lyman- α and other strong emission lines seen in high redshift quasars and confirms the low ratio of Lyman- α to H α which may be due to dust in the line-emitting region or some other causes. The flux at the Lyman continuum limit (important as an input datum for photoionisation models of the line-emitting region) can be estimated from a small extrapolation of the observed continuum, and the absence of an absorption trough on the short side of Lyman- α enables the previous very stringent limit on the abundance of neutral hydrogen in intergalactic space to be extended to recent cosmological epochs.

A traditional preoccupation in extragalactic astronomy is the determination of the deceleration parameter q_0 , the basis of the method being to plot the redshifts of 'standard candles' against

their apparent brightness so that deceleration manifests itself as an upward curvature in the relation at the faint end. The favoured choice for standard candles is to use first-ranked elliptical galaxies in clusters, but these are restricted to redshifts less than about 0.5 and raise the problem of the effect on their luminosities of stellar evolution during the look-back time; so all that one can say with confidence from present data is that q_0 is fairly small, between -1 and $+1$, say. Indirect arguments, based on the large cosmic abundance of deuterium, suggest that q_0 is positive and under 0.1, well below 0.5 which is the boundary between a 'closed' and 'open' Universe.

Recent work on high redshift quasars has suggested that there may, in fact, be a method of finding standard candles among quasars, based on the equivalent width of Lyman- α , and perhaps one or two other emission lines, in those objects which are flat-spectrum radio sources. Since 3C 273 is a member of this class, Davidsen *et al.* have been able to use their measurement of Lyman- α to tie it in to the system of standard candles based on objects with redshifts up to 3.39 and thus to deduce that $q_0 = 1$ with an impressive internal precision, but with a possibility of systematic error which the authors are careful to point out. A further point that might be made is that the fact of their getting a reasonable value of q_0 at all by this method is evidence in favour of the cosmological interpretation of the redshift.

Probably the most significant result of all in the Johns Hopkins experiment relates to the nature of the absorption lines seen in quasars of high redshift. These fall into two classes: lines seen close to (and usually on the blueward side of) the emission lines, which can be very broad and are almost certainly a 'P Cygni' effect of absorbing gas coming out from the quasar itself (Class I); and Class II absorption lines (including occasionally the 21-cm line of neutral hydrogen), seen at much

B. E. J. Pagel is Professor of Astronomy at the University of Sussex, and is at the Royal Greenwich Observatory, Hailsham, Sussex.

lower redshifts than the emission lines, which are narrow, are formed under low-excitation conditions and can exist in many different redshift systems in the spectrum of one object. The nature of the Class II absorption lines is highly controversial. Riva hypotheses state on the one hand that they are due to material ejected from the quasar at speeds up to 0.6 c ; and on the other that they are due to diffuse interstellar gas in unseen intervening galaxies at the normal cosmological redshift. The second hypothesis is favoured by the distribution statistics of number of systems in one object and by the resemblance between the absorption-line spectra and that of the interstellar medium in our own neighbourhood, but requires the extent of interstellar gas in at least some galaxies to be larger than expected. The presence or absence of Class II absorption lines (which are chiefly

seen shortward of Lyman- α) in 3C 273 provides a critical test between these two hypotheses, because 3C 273 is as luminous as at least one of the high redshift quasars in which several absorption-line systems are seen and is presumably very similar to them physically so that it is equally capable of expelling matter; but it is so near to us that the probability of an intervening galaxy being present is negligible.

Although the spectral resolution of the experiment of Davidsen *et al.* is too low to detect individual absorption lines, the number of lines in high redshift objects is so great as to produce a depression of about 30% in the continuum below Lyman- α , and this can still be easily detected at low resolution. The observed depression in 3C 273 is only $2 \pm 6\%$, which provides an impressive argument in favour of the intervening-galaxy hypothesis. \square

Cell transformation with herpes simplex viruses

from Franklin H. Portugal

HERPES simplex virus, one type of which causes cold sores and another genital tract infections, is receiving increasing attention as a model for understanding how virus expression leads to host cell transformation. In certain conditions infection of mammalian cells with HSV leads to a non-productive infection in which only part of the viral genome is expressed. When mouse cells lacking the enzyme thymidine kinase are transformed by ultraviolet-irradiated HSV, the cells develop thymidine kinase activity which is coded by the virus and which can be distinguished from the host cell enzyme by various biochemical criteria. So far cells transformed in this way cannot be induced to release infectious virus, suggesting that a fragment of the viral genome, although unable to produce infectious virus, is able to maintain the virus-transformed phenotype. Nucleic acid hybridisation indicates that in mouse cells infected with irradiated HSV-1, either five copies of about 23% of the viral genome (Kraiselburd, Gage & Weissbach *J. molec. Biol.* **97**, 533; 1975) or four to six copies of a 10% fragment of the viral genome (Davis & Kingsbury *J. Virol.* **17**, 788; 1976) are present. Hamster cells transformed by irradiated HSV-2 seem to

contain one to three copies of between 8% and 32% of the viral genome (Frenkel *et al. J. Virol.* **18**, 885; 1976). It is not yet known whether the viral genes become integrated into the host chromosome or remain in the cytoplasm.

Maitland and McDougall (*Cell* **11**, 233; 1977) now report that they have been able to transform mouse cells lacking thymidine kinase activity with DNA fragments produced from HSV-2 DNA either by specific cleavage with restriction endonucleases or by mechanical shearing. The transformed cells were selected by their ability to grow in medium containing hypoxanthine, aminopterin, and thymidine, which indicates the presence of a thymidine kinase-positive cell. The cells contained the virus-induced enzyme as well as HSV-specific immunofluorescence. The DNA fragments produced by endonuclease cleavage can be located on a map of the HSV-2 genome and from this information, the thymidine kinase gene seems to be located in the long segment (L region) of the viral genome. Wigber *et al.* (*Cell* **11**, 223; 1977) report the transformation of thymidine kinase-negative mouse L cells with a *Bam*I endonuclease restriction fragment of HSV-1. Cells treated with *Eco*I restriction fragments were not transformed. Bacchetti and Graham (*Proc. natn. Acad. Sci.*

U.S.A. **74**, 1590; 1977) also report that thymidine kinase-negative human cells can be transformed by mechanically sheared fragments of HSV-2 DNA. Several lines of transformed cells have been established that grow continually in the selection medium, express thymidine kinase activity of viral origin, and differ in the stability of thymidine kinase expression.

As well as thymidine kinase, a recent study suggests that a new species of another enzyme, deoxycytidine deaminase, is induced when mammalian cells are lytically infected with HSV-1 (Chan *Proc. natn. Acad. Sci. U.S.A.* **74**, 1734; 1977). The results strongly suggest that this enzyme is also coded by the virus. This study is of particular importance because the induced enzyme may affect cytosine arabinoside, a drug commonly used to treat HSV infections, thus making it less effective.

The fact that specific fragments of the HSV genome, coding for clearly defined biochemical functions, can transform mammalian cells suggests that the HSV system will become an increasingly important model for defining those genes required for both biochemical and morphological transformation. In addition, this system has already begun to provide evidence for the mechanisms that control the viral genome in mammalian cells. This information will presumably be of use not only for specific chemotherapy of human HSV infections but also for understanding virus transformation in general, including oncogenic transformation. Furthermore, it may eventually become feasible to use the HSV model for DNA-mediated gene transfer between mammalian cells. \square

Electron storage rings as lasers

from John Pendry

A NEW mechanism for laser action has been demonstrated by a research group working at the Stanford linear accelerator (Deacon *et al. Phys. Rev. Lett.* **36**, 892; 1977). The device is built on the theory that an electron deflected by a magnetic field can emit stimulated as well as incoherent radiation. So far the device has worked in a pulsed mode extracting 7 kW peak power of laser radiation from the kinetic energy of the electron beam. It appears that only

John Pendry is Head of the Theoretical Physics Group at the Daresbury Laboratory.

Franklin H. Portugal is Associate Managing Editor of the Proceedings of the National Academy of Sciences.

about 0.2% of the electron's kinetic energy can be extracted in each pass through the magnets but it is planned to increase the efficiency by circulating the electrons in a storage ring, which should also raise the mean power available.

Conventional electron storage rings have a large amount of power pumped into them which is dissipated in the incoherent synchrotron radiation. Ultimately this new laser, fixed to a storage ring, could conceivably channel a substantial fraction of the power into stimulated radiation making it available as a well collimated beam of fixed wavelength.

In a conventional laser transitions are stimulated between electronic states of atoms. The power is limited by the pumping process for energising the atoms, and the frequency by availability of suitable electronic transitions. Only recently have continuously tunable lasers become available and the range of tuning is limited to typically less than 1% of the operating wavelength. In the new process massive amounts of energy are available in the kinetic energy of the electron beam and the wavelength of radiation can be simply varied by a large factor. It is expected that lasing action can be observed at wavelengths varying from a few 100 μm down to 0.1 μm .

The laser operates by passing the electron beam through a helical magnetic field. If the spontaneous radiation is confined in a cavity, it can stimulate further radiation, the gain peaking at a wavelength

$$\lambda_s = \frac{\lambda_q}{2\gamma^2} \left[1 + \frac{1}{(2\pi)^2} \frac{\lambda_q^2 r_0 B^2}{mc^2} \right]$$

where λ_q is the period of the helix, B the magnetic field strength, c the velocity of light, r_0 and m the classical electron radius and mass of the electron respectively; the electron energy is γmc^2 . The electron chases closely after the emitted radiation with almost the velocity of light so that pulses from successive periods of the helix fall very close together and the wavelength of radiation is much shorter than the helix period. A 3.2-cm period helix and 43.5 MeV electron beam generate 3.4 μm radiation. (The helix used in the experiment was 5.2 m long.) It is this relativistic shift of the wavelength which gives the laser its great tunability. The energy of the electron beam being proportional to γ , the operating wavelength, λ_s , scales inversely as the square of the energy.

The immediate difficulty is that the laser requires high currents to produce usable gain, posing problems of stability in storage rings operating at what are

rather low electron energies. The theory of storage rings is well understood and these difficulties can probably be overcome to a satisfactory extent. Less well understood is the perturbation that the huge radiation fields building up in the cavity will have on the electron orbits. Even in these preliminary experiments $\frac{1}{2}$ MW of peak power was present in the cavity and this amount of radiation could possibly upset the operation of a storage ring.

Devices producing large amounts of power over a wide spectral range are bound to find wide application. It is conceivable that one of the first uses might be as a tunable source of infrared radiation. Current sources tunable in the 20–200 μm range are of very low power, 10 mW or less, whereas the free electron laser has already functioned at an average power of 0.36 W. Spectroscopy in the far infrared would be vastly improved by the availability of even 1 W of power. Experiments on semiconductors would have the sensitivity to measure excitonic and impurity spectra. Many transient species occurring in fast reactions or in the stratosphere would become accessible to laboratory infrared spectroscopy, and infrared studies of surfaces would be much extended in their capabilities if the weaker absorbers of radiation could be detected.

If the free electron laser can be further developed to give very high powers approaching the megawatt c.w. range sufficient power would be available to consider photochemical reactions and isotopic separation on an industrial scale. In the laboratory large amounts of radiation could be used to shift populations of states on a macroscopic scale giving rise to non-linear phenomena. But it is probably true that the most valuable uses of such a source are yet to be discovered. \square

Planetary crater retention ages

from David W. Hughes

ABSOLUTE ages of planetary features can be determined in principle by dividing the observed crater number density N by the crater production rate, F . So age = N/F . William K. Hartmann (Planetary Science Institute, Tucson, Arizona) is of the opinion that 'the emphasis in funding, research and publication is all on the numerator and none on the denominator' in the above

David W. Hughes is a Lecturer in the Department of Physics at the University of Sheffield.

Correction

In the article 'Multispecific antibodies' (*News and Views* 268, 689; 1977) column 2, page 690, paragraph 2, line 4 should read: "The 'best' antibodies bind their antigens with avidities of 10^7 – 10^9 1 mol^{-1} but so far multispecificity has only been observed in the $\leq 10^6$ 1 mol^{-1} range."

equation. He aims to remedy this state of affairs by his recent paper in *Icarus* (31, 260; 1977).

First let us deal briefly with the numerator. The literature abounds with papers giving details of how N varies with diameter D . Researchers have obtained photographs of lunar and planetary features from Orbiter, Surveyor, Apollo and Mariner spacecraft and have simply counted N , the number of craters per square kilometer with diameters in the range D to \sqrt{D} km. N is proportional to D^n where $n = -2.0$ for lunar maria and the Tharsis plane of Mars, regions where there has been little disturbance. Erosion, which removes smaller craters, gives n values between -1.3 and -1.8 . On the slopes of Olympus Mons, the Martian volcano, $n = -2.4$, possibly due to small volcanic pits adding to the impact craters. To give some impressions of the numbers involved, a typical lunar maria which has been exposed to impact bombardment for about 3.4 aeons (an aeon is 10^9 yr) would have about 10,000 craters larger than 1 km in diameter and 10^{13} larger than 10 cm, in an area of 10^6 km^2 .

Hartmann deals with F , the crater production rate in considerable detail. F is a function of crater diameter, time from the origin of the Solar System, heliocentric distance and planetary size. The diameter dependence is fairly well understood and a similar power law dependence has been found for crater populations on young undisturbed plains on Mercury, Mars and the Moon. The dependence is consistent with the power law size distribution of asteroids, comets and meteorites, these being the impacting bodies responsible for the craters.

The time dependence is based on Apollo chronologies. F was at least hundreds of times higher than its present value before 4 aeons ago but has been within a factor of 10 of present day values during the past 3 aeons. Most people regard the time dependence as representing a smooth transition from the chaotic state of affairs during planetary accretion to the present day near steady state depletion of the asteroid and comet reservoirs. F would be expected to have roughly the same time dependence for all planets.

The change in F as one goes from one planet to another is virtually unknown and is the primary subject of Hartmann's paper. He bases his calculations on a study made by G. Wetherill (*Proc. Lunar Sci. Conf.* 6, 1539; 1975) who considered families of planetisimals in specific orbits and then proceeded to compute the relative number of impacts from each family onto the surfaces of the different planets. The first step is to consider a meteorite of a specific mass and to calculate the diameter of the impact crater it would produce on Mercury, Venus, Earth, Moon, Mars and so on. Obviously the meteorite's orbital velocity (and thus energy) will increase as it moves in towards its perihelion. The effect that the planetary gravitational attraction has on this velocity also varies (this is proportional to $\sqrt{M/R}$ where the planet has a mass M and a radius R). The more massive planets also have a larger effective collision cross section and can sweep up more impacting bodies. Four orbital families are considered, ancient planetisimals circling planets (these only hit planetary satellites), ancient planetisimals circling the Sun (these two families having low relative velocities), asteroidal and short period cometary bodies making up a medium velocity family and long period comets, a high velocity family. In the case of the Moon the impact velocity of a typical member of each of these families would be about 3, 6, 14 and 38 km s^{-1} respectively. The calculated F values from each source onto each planetary and satellite body turn out to be remarkably similar and Hartmann concludes that the terrestrial planets have crater production rates within a factor of 10 of each other. No planet seems to have a preferential source of impacting bodies. The Mercurian crater production rate is about 0.8 to 5 times the lunar rate indicating that Mercury's lava plains, which have N values equal to their lunar counterparts, are in fact younger. Venusian and terrestrial cratering rates are about 1 to 2 times the lunar rate, the surface of Venus having a retention age for 100 km scale craters of around an aeon. Martian production rates are between 1 and 7 times higher than lunar rates; more of this later. The satellites of the outer planets have crater production rates less than a tenth the rate of lunar cratering and should be considerably smoother. There seems to have been no major fluctuations in these rates over the past 3 aeons, and Hartmann concludes that the planetary crater retention ages of surface features formed during this time can be determined within an uncertainty factor of 3 in either direction.

The calculations discussed above have been applied specifically to

Martian crater counts. By scaling to a typical lunar maria the age of a Martian feature, T , is given by

$$T = 3.4 (N_{\delta} / N_{\text{L}}) (F_{\text{L}} / F_{\delta}) \text{ aeons}$$

The channels on Mars are found to have ages of 1 aeon (the uncertainty factor making this range between 0.3 and 3 aeons). The Tharsis plain, a broad equatorial region which surrounds four volcanoes, is slightly younger, about 0.8 aeons old. Olympus Mons is about 0.2 aeons old. These latter findings are contrary to recent assertions by G. Neukum and D. U. Wise (*Science* 194, 1381; 1976) who find that Olympus Mons is 2.5 aeons old and most Martian volcanic provinces older than 3 aeons. Hartmann puts forward a hypothetical Martian scenario in which liquid water was much more abundant on Mars before the Tharsis volcanism started. This volcanism caused a variation in the obliquity of Mars which switched greenhouse effects on and off forming and remelting permafrost layers. This continued until the current Tharsis surface was formed which fixed the obliquity at its present value and resulted in the present state of nearly permanent cold dryness.

Two things are needed to refine the study of crater production rates. First the number of velocity and orbital families considered must be increased and statistical calculations must be made to give a more accurate estimate of the final impact site of bodies in these families. Second, more asteroidal and cometary surveys must be undertaken so that more accurate estimates can be made of the numbers of bodies in each orbital family. With this knowledge the uncertainty factor of 3 in the crater retention ages can one hopes be much reduced. \square

Irrepressible superconductor

from Robert W. Cahn

THOSE who study superconductors with practical ends in mind have been much concerned to raise the transition temperature and the critical magnetic field: indeed, one sometimes has the impression that a transition temperature at or above ambient represents the philosopher's stone for some of today's physicists. There is however another, less regarded material property which limits potential applications, and that is the critical current density, itself a function of field and a structure-

sensitive property. Nb_3Al is one of the most promising A-15 superconductors because of its extremely high critical field ($H_{c2} = 295 \text{ kG}$ at 4.2 K), but the critical current density is modest, and various metallurgical tricks used by a number of investigators to modify the microstructure have in the past not been very effective in improving the situation. About 10^5 A cm^{-2} is the best that has been achieved. A completely new approach now promises the engineer an excellent new superconductor.

K. Lo, J. Bevk and D. Turnbull (*J. appl. Phys.* 48, 2957; 1977) of Harvard University decided to melt-spin the alloy. 'Melt-spinning' is the name given to a variant of splat-quenching which produces a thin continuous ribbon of alloy. The version used here involves a rapidly rotating copper saucer—the substrate—on to which a fine stream of molten alloy is projected. The investigators found that a small silicon addition was needed to produce a good ribbon: their alloy was of composition $\text{Nb}_{73}\text{Al}_{25.5}\text{Si}_{1.5}$. Hitherto, melt-spun ribbons have been used to examine mechanical or ferromagnetic behaviour: melt-spun superconductors are something new under the Sun.

The thickness of the ribbon and thus the effective quenching rate can be modified by altering the speed of rotation of the substrate: the thinnest ribbon was $25 \mu\text{m}$ in thickness and had grains $< 0.5 \mu\text{m}$ in diameter. The microstructure consisted of fragments of dendrites surrounded by transition layers presumed to be of variable composition. The crystal structure remained single phase A-15. To measure electrical characteristics, the samples had to be embedded in indium in order to provide good electrical and thermal connections. Even so, the contact resistance limited the feasible current density to $1.8 \times 10^6 \text{ A cm}^{-2}$. $25 \mu\text{m}$ ribbons were tested in fields up to 150 kG and the critical current density was found to be in excess of the experimentally enforced limit of $1.8 \times 10^6 \text{ A cm}^{-2}$ in all field strengths. When the ribbon was annealed at 750°C , T_c was raised from $\sim 16 \text{ K}$ to 18.4 K and the critical current density was still in excess of the experimental limit. (It is therefore not known whether heat treatment increased or decreased the critical current density). The highest critical current density in 105 kG for Nb_3Al (that is, the highest in any substance) reported in the past was $\sim 10^5 \text{ A cm}^{-2}$. Plainly an extreme refinement of microstructure is the key to an enhanced critical current density.

It is already clear, from these preliminary results with just one of the A-15 family of compounds, that a new generation of high-field super-

Robert W. Cahn is Professor of Materials Science at the University of Sussex.

conductors is in the offing. There will of course be problems—principally the need to incorporate superconducting ribbons into a thermally well-conducting matrix such as copper to provide insurance against a breakdown of superconductivity in service. A number of metallurgical techniques are available for this purpose (for example, Tsuei *J. appl. Phys.* **45**, 1385; 1974; Chen & Tsuei *ibid.* **47**, 715; 1976) but they generally depend on a precipitation of superconducting filaments *in situ*. Melt-spun ribbons will have to be incorporated in a matrix after they have been made: it may be possible to use a sintering technique with a low-melting metal such as aluminium. The fact that annealing does not damage the superconducting properties will simplify the task.

Rapid quenching from the melt has been used before in connection with superconduction, but in a different sense. Instead of using the technique to refine the structure of a stable compound, as the Harvard scientists have

done, workers at California Institute of Technology used it to create metastable structures. Johnson and Poon (*J. appl. Phys.* **45**, 3683; 1974) tested a whole range of metastable simple cubic inter-metallic superconductors (such as $\text{Te}_{70}\text{Au}_{30}$, $\text{Sb}_{75}\text{In}_{25}$) and established that T_c was systematically (and inversely) related to lattice parameter; $\text{Sb}_{75}\text{Au}_{25}$ had the highest T_c of ~ 6.5 K, and it seemed that the (meta) stability of the simple cubic lattice (one atom per unit cell) broke down for smaller lattices. Glassy alloys, made by melt-spinning, can also be superconducting: V. L. Johnson, S. J. Poon and P. Duwez (*Phys. Rev.* **B11**, 150; 1975) examined the superconductivity of $\text{Au}_{25}\text{La}_{100-x}$ glasses ($16 \leq x \leq 40$). Among other peculiarities, these glasses have ultra-short electronic mean free paths. For $\text{Au}_{25}\text{La}_{75}$, this path is 1.7 \AA , $T_c = 3.4$ K, the upper critical field ~ 10 kG. This category of material is a scientific curiosity but is not likely to threaten the technological superiority of Nb_3Al and its analogues. □

tion of heat sources is uncertain and must be assumed, albeit on the basis of reasoned geological and petrological arguments. In practice, Chapman and Pollack take an upper layer of 8 km with heat production A overlying a granulite facies lower crust of 32 km with heat production $0.25 \mu\text{W m}^{-3}$ overlying a depleted ultrabasic zone (80 km, $0.01 \mu\text{W m}^{-3}$) overlying a pyrolyte mantle ($0.084 \mu\text{W m}^{-3}$). In this context, A , the heat production in the upper crust, is the variable related to surface heat flow. By inserting different values of regional surface heat flow it is then possible to derive a series of geotherms for the continental lithosphere (making another assumption, again reasoned, on the variation of thermal conductivity with temperature).

The approach to the oceanic area, however, is rather different. Here the thermal regime is characterised by cooling following formation at a spreading ridge, although the oceanic lithosphere will also contain radioactive sources. Chapman and Pollack assume an initial temperature gradient of $1,300^\circ\text{C} + 1.5^\circ\text{C km}^{-1}$ and a heat production of $0.5 \mu\text{W m}^{-3}$ in the upper 10 km in deriving a family of oceanic geotherms in which the variable is again regional heat flow. And finally there is the question of the mantle solidus, for which assumptions are again necessary because of the uncertain role of volatiles in depressing solidus temperature. In fact, Chapman and Pollack go for a mixed volatile environment (chiefly H_2O and CO_2) which leads to a solidus intermediate between those applicable to volatile-free and purely hydrous melting.

Implicit in all this, of course, is the hope of an ultimate relationship between (regional) surface heat flow and lithospheric thickness which can be defined accurately and smoothly enough to enable the latter to be determined from the former. And such a relationship indeed emerges. From the intersections of the derived geotherms with the adopted solidus, Chapman and Pollack are able to obtain smooth curves (one each for continental and oceanic zones) of lithospheric thickness against heat flow. Moreover, where comparable direct data on lithospheric thickness are available (for example, for the Pacific and North America) the agreement between observation and the predicted curves is good, thus justifying the assumptions made in the first place. With this encouragement it is then but a short step to convert the world map of the 12th degree spherical harmonic analysis of global heat flow developed earlier by Chapman and Pollack (*Earth planet. Sci. Lett.* **28**, 23; 1975) into a parallel map of world lithospheric thickness.

Thickness of the lithosphere

from Peter J. Smith

FOR more than 50 years the Moho was regarded as the most important discontinuity in the upper Earth, and following its discovery by Andrija Mohorovičić in 1909 considerable effort was devoted to determining its depth throughout the world. The result is that worldwide contour maps, albeit imperfect ones, of crustal thickness have been around now for some time. But although the Moho is no less fundamental a boundary than it ever was, its significance has been overshadowed in recent years by that of the lithosphere–asthenosphere interface. The fact is that as far as plate tectonic processes are concerned, the crucial contrast is not the physicochemical one between the crust and mantle but the physical one between the lithosphere and asthenosphere.

So how thick is the lithosphere? A rapid and random survey of published opinions suggests that the top of the asthenosphere is most commonly thought to be 'about 70 km deep', although it is widely recognised that this is an average concealing variations. In this latter respect lithospheric thickness resembles crustal thickness; but the similarity ends there. The lithosphere–asthenosphere boundary appears to be less sharp than the Moho and thus more difficult to locate

accurately. Moreover, there are far fewer spot measurements of asthenospheric depth than of mantle depth because of the relatively recent origin of interest in the former. Certainly no one has yet suggested that there are sufficient direct data for the production of a worldwide contour map of lithospheric thickness.

Nevertheless, Chapman and Pollack (*Geology*, **5**, 265; 1977) have now produced just such a map. Of course, their approach has had to be indirect. Specifically, they have developed a thermal model of the lithosphere which has enabled them to derive a family of geotherms for continental and oceanic zones in which the principal independent variable is surface heat flow. The depth at which these geotherms intersect the mantle solidus is then taken as the surface of the asthenosphere. The point about all this is, of course, that surface heat flow and its variations throughout the world are now quite well known, so the problem of the primary data is largely solved.

On the other hand, there is a disadvantage in that, as with all indirect methods, it is necessary to make assumptions. For example, the continental model adopted by Chapman and Pollack not surprisingly involves steady state conduction through a lithosphere which contains radioactive heat sources and into which heat flows from below. But the vertical distribu-

What the new map shows is that the thickness of the lithosphere varies from a few tens of kilometres in young oceans and continental orogenic provinces to more than 300 km in shield areas. It is also evident from the analysis which led to the production of the map that beneath the continental shields the asthenosphere is very thin. Indeed, a strict interpretation would suggest that the asthenosphere does not exist there at all, for shield geotherms do not intersect the solidus at any depth, although shield lithosphere is presumably partially decoupled from the deeper interior at the depth at which the appropriate geotherm approaches the solidus most closely. In any event, there is a clear implication that the viscous drag at the base of shield lithosphere is much higher than elsewhere—a prediction which receives some support from observation.

Finally, it is clear that the thickness of the lithosphere, both continental and oceanic, increases (not linearly) with age. This implies that shield lithosphere was once much thinner than it is now and that the asthenosphere beneath it was thicker, thus facilitating continental drift during the Precambrian. As for the future, continental lithosphere will presumably continue to thicken, increasing the viscous drag at its base and thus gradually bringing drift to a halt. □

Communal nesting in birds

from John Krebs

THE Central and South American Groove-billed Ani (*Crotophaga sulcirostris*) lives in groups of one to four monogamous pairs. All the females in a group lay their eggs in a communal nest, and both members of each pair help to incubate and feed the young. The axiom of selfish genery warns one to expect that Ani groups are uneasy alliances in which each individual pursues its own reproductive ends. A study recently reported by S. L. Vehrencamp (*Science* **197**, 403; 1977) reveals that this is indeed the case. The most obvious and unequivocal sign of self interest is that the females in a group roll each other's eggs out of the communal nest. Females cannot, however, distinguish their own eggs from those of others so that an individual only engages in egg-rolling before she herself has started to lay. This means, of course, that the first female to start

laying eggs is more likely to suffer, and the last female to start loses no eggs. Although the first female(s) to lay to some extent compensate for egg loss by laying larger clutches, they still end up with fewer eggs than the last female at the time of incubation. In comparing nesting groups of different sizes, Vehrencamp found that the average number of eggs per female is positively correlated with group size, but the first female to lay in the group raises fewer young than a solitary pair, while the last female raises more. So far all the benefits seem to lie with the last female to lay and none with the first. There is potentially a cost to the late layer, because the first female starts to incubate as soon as she has completed her clutch, and the first young to hatch out survive better than later ones. The late female's answer to this is to lay her eggs more rapidly, at 1–2 day intervals compared with 2–3 days for early females, so that her young hatch out no later than average. All in all, the late females clearly do better than early layers, and they tend to be older (probably more dominant) individuals who are mated to larger than average males.

The late layers also gain when it comes to parental care: they contribute less to incubation and feeding the young than do the other females in a group even though most of the brood is theirs. This picture of more or less parasitic behaviour by late females is to some extent ameliorated by the fact that the males mated to late layers do more incubation and feeding of the young than any other group member. This implies that the male can tell that his mate has laid most of the successful eggs so that he is feeding his own children.

Clearly we need to know a lot more about the Ani system of communal nesting before a full cost benefit analysis for each group member can be done. At the moment it looks as though the late-laying female and her mate get more out of the system than the others, so further data are needed to work out why the communal nesting system is a stable, if selfish alliance.

In other communal nesting species which have been studied over several years, the members of a group are usually closely related to one another. However, these species, including babblers of the genus *Turdoides* and two American jays (*Aphelocoma* spp.), have a different system of communal nesting from that of the anis. Only one pair does all the reproducing, and the other group members are usually sub-adults, many of them offspring of the reproductive pair and hence siblings of the present nestlings. Although the helpers, as they are called, may in-

dators, and feed nestlings, there is some uncertainty about how much they actually increase the reproductive success of the breeding pair (Zahavi *Ibis* **116**, 84; 1974; Woolfenden *Auk* **92**, 1; 1975; Gaston, thesis, Oxford, Univ. 1976). One interpretation (Gaston *op. cit.*) is that the helpers are providing just enough aid to encourage the parents to allow them to stay in their territory. In both the babblers and jays, young birds have rather little chance of establishing their own territory away from home, because the suitable habitat is fully occupied by adults, who have a low mortality rate. The best bet for a young bird is to stay at home and try to take over the parental territory when one or both of the parents die.

In doing this, the young birds could reduce the future reproductive success of their parents by competing for food, attracting predators to the nest, and so on. In order to offset this, and hence make it profitable for the parents to allow them to stay, they provide a small amount of help in rearing new young.

This interpretation is speculative, but it emphasises that the apparently simple cooperation probably has a rich and fascinating underlying pattern of selfish behaviour. □

A hundred years ago

METEOROLOGY AND THE INDIAN FAMINE . . . Dr Hunter also found that six great scarcities of sufficient gravity to be officially returned as "famines" had occurred during the period 1880–77. Of these six famines five were caused by years of drought coincident with, or adjoining to, the periods of minimum sunspots. He further showed that the rainfall at Madras passed through an eleven year's cycle, corresponding with the cycle of sun-spots. That is to say, the rainfall reaches its minimum in the eleventh year, rises to its maximum about half-way through the cycle in the fifth year, and then declines again to its minimum in the eleventh year.

At the recent biennial meeting of the German Astronomical Society, which was held at Stockholm, the members received the news of the discovery of the two satellites of Mars with manifestations of grave doubts. The president at their request telegraphed to the Berlin Observatory, and in reply received a copy of the original telegram as it was sent from America.

Carbon fixation pathways

from Sandy Grimwade

A symposium on the C_3 and C_4 photosynthetic pathways was held by the Ecological Society of America at the Annual Meeting of the American Institute of Biological Science in East Lansing, Michigan in August 1977.

THE fixation of atmospheric carbon dioxide into metabolic intermediates by green plants can take place by three different pathways. In the majority of plants CO_2 is fixed by the classic Calvin cycle directly into ribulose diphosphate to form two molecules of phosphoglycerate—a three-carbon compound. In some plants, however, the initial carboxylation step results in the formation of C_4 compounds such as oxaloacetate, which are then decarboxylated in specialised bundle sheath cells where the released CO_2 is refixed by the usual Calvin cycle. The third, and most restricted type is found mostly in succulents of arid regions. Fixation of CO_2 in this case occurs into crassulacean acid.

The differences between the so-called C_3 and C_4 plants give rise to a wide variety of biochemical, ecological and climatological implications, some of which were discussed at the symposium.

B. N. Smith (Brigham Young University) outlined the biology of C_3 and C_4 plants and the resulting isotope fractionation effects. Atmospheric CO_2 contains both the ^{12}C and ^{13}C stable isotopes of carbon. Compared with a standard limestone sample, the relative concentration of the ^{13}C isotope in atmospheric CO_2 ($\delta^{13}C$) is -7% . The photosynthetic fixation of atmospheric CO_2 exhibits a substantial isotope effect, which differs markedly for C_3 and C_4 plants. As CO_2 fixation is the only reaction which shows such a substantial effect, the resulting isotope depletions are reflected throughout the plant tissues. In C_3 and C_4 plants, the $\delta^{13}C$ values are -26 and -12% respectively. In addition, these isotope depletions are maintained in the herbivores which eat the plants and so on up the food chain. As these differences are so marked, they provide a valuable tool in several fields. For instance, the relative concentration of C_3 and C_4 plants in fossil animals can be estimated. The adulteration of honey—mostly from C_3 plants—with

corn syrup, from a C_4 plant, could be detected and quantified.

Any consideration of C_3 and C_4 metabolism in plants gives rise to two related questions—why do plants use more than one pathway for CO_2 fixation and how did the pathways evolve. Answers to these questions must account for the fact that C_4 metabolism is found spread throughout many plant genera, and yet no genus is composed exclusively of C_4 plants. For instance, about 50% of grass species are C_4 plants as is a smaller proportion of Compositae. The only way to account for such a patchy distribution is to hypothesise that C_4 metabolism with its attendant array of specialised enzymes and cellular anatomy arose as many as 20 times in the course of plant evolution. The alternative proposition, that it arose once or a few times is almost impossible to reconcile with accepted schemes.

The question of the rationale for more than one pathway is easier to tackle. J. R. Ehleringer (Stanford University) presented data showing the advantages of C_4 metabolism in grasses in particular environmental circumstances. Measurements on whole plants of net carbon gain per unit weight show the following. At normal oxygen tension, C_3 and C_4 plants show similar efficiencies, but as O_2 tension decreases, the efficiency of C_4 metabolism increases whereas C_3 remains constant. Similarly, the yield of C_4 plants is constant with increasing temperature whereas the efficiency of C_3 metabolism decreases. C_4 plants also have the advantage at high light intensities and low humidity. Using these data, a computer simulation of the rate of carbon gain in a C_3 or C_4 grass canopy in the Great Plains of the United States in July shows that as latitude increases, so does the efficiency of C_3 grasses. At $45^\circ N$ the two types are about equal. A survey of the flora of the Great Plains reveals that in the south of Texas ($25^\circ N$) about 70% of the grass cover is C_4 , at $40^\circ N$ the two types are equal, and at $60^\circ N$ only C_3 types are found. Thus the relative physiological advantage of C_3 or C_4 metabolism is directly reflected in the flora of the region.

Similarly, a survey by C. T. Harrison (University of Wyoming) of the grass types along a transect of grasslands in Wyoming shows a decrease in the percentage of the biomass composed of C_4 grasses with increasing elevation, and hence decreasing average temperature. This point is nicely reflected in measurements of the $\delta^{13}C$ values of bison remains in a single burial pit in Wyoming. At the surface, the $\delta^{13}C$ values reflect a diet for the bison which contains a substantial proportion of C_4 grasses. With increasing depth,

and hence age, the proportion of C_4 in the diet decreases until the $\delta^{13}C$ value reflects a diet composed entirely of C_3 plants approximately 8,000 years ago. This is held to reflect the gradual warming of the climate, with the subsequent invasion of C_4 grasses from the south over the past few millennia. \square

Gravitation but no levitation

by Malcolm MacCallum

The Eighth International Conference on General Relativity and Gravitation was held at the University of Waterloo, Ontario, Canada on 7–12 August, 1977. The organising committees, headed by M. McKiernan (University of Waterloo) and W. Israel (University of Alberta, Edmonton), provided a most enjoyable and enlightening meeting.

'GR8' proclaimed the T-shirts: they were right in more ways than one. Up to nine parallel afternoon sessions were required to accommodate more than 400 talks contributed from among the 700 or so participants. The morning plenary sessions were devoted to invited talks, mainly reviews.

Informal discussions between V. Braginsky (Moscow), W. Unruh (University of British Columbia, Vancouver) and others evolved schemes to push the sensitivity of gravity wave detectors to the level where the instrument must be regarded as a quantum system. A factor of about one million improvement is required to measure the expected astrophysical sources, as described by K. S. Thorne (Caltech). The active groups developing the various possibilities were all represented, and there seemed to be considerable optimism about the feasibility of the new detectors and the likely technological spin-off from their development.

Experimental results by I. S. Shapiro (Massachusetts Institute of Technology) on time-delay data from the Viking missions to Mars, and by R. B. Partridge (Haverford College) on the isotropy of the cosmic microwave background contained no real surprises, apart from some unexplained and unsystematic deviations in Shapiro's data which he tentatively ascribed to procedural errors at the tracking stations. R. Newman (University of California,

Irvine) described new laboratory tests confirming the inverse square law at ranges around 4 cm in contradiction to some results of Long (*Nature* **260**, 417; 1976).

The ever-expanding capabilities of computers were much in evidence, and I suspect many relativists will have been converted to a new interest in the potential of the algebraic manipulation systems, most of which, such as the SHEEP system demonstrated by I. Frick (University of Stockholm), are designed for ease of casual use. Interesting numerical computations included two splendid films, by J. R. Wilson (Lawrence Livermore Laboratory) on collapse and by L. Smarr (Harvard University) and K. Eppley (University of Maryland) on the head-on collision of two equal mass black holes. Thorne suggested that generalisation of the latter to glancing incidence might increase the rather low gravitational radiation found by Smarr and Eppley.

The significance of black holes for astrophysics and cosmology was well reviewed by M. J. Rees (Institute of Astronomy, Cambridge) and I. D. Novikov (Moscow) respectively. Effects considered ranged from X rays through quasar models to the overall entropy of the Universe, and included the polarisation effects recently predicted by P. A. Connors and R. F. Stark of the University of Oxford (*Nature* **266**, 429; 1977). Among the other astrophysical contributions, J. L. Friedman (Wisconsin-Milwaukee) announced that all rotating stars are unstable, and C. M. Caves (Caltech) pointed out that gravitational Cerenkov radiation would cut off the cosmic ray spectrum in some alternative theories of gravity.

The singularities symposium consisted of many informal contributions, shorter even than their written abstracts, carefully organised by G. F. R. Ellis (University of Capetown) into an enlightening overview. The difficulties in defining singular boundary points and in formulating the 'cosmic censorship' hypothesis (roughly, that all singularities other than an initial big bang are hidden inside black holes) were well discussed. In the session on the initial-value problem Y. Choquet-Bruhat (Paris) reviewed her work with J. Marsden (University of California, Berkeley) proving that the energy of asymptotically flat spaces has a minimum, namely zero, at flat space, thus partially verifying the long-standing conjecture that such spaces have positive energy.

Complex variable techniques figured in various contexts. W. Kinnersley and D. M. Chitre (Montana State University) have developed a method for generating infinite families of solutions

of Einstein's equations. R. Penrose (University of Oxford), in his review, related his twistor programme to the soliton solutions of Yang-Mills theory.

The various schools of thought on quantum gravity were well represented. The most rapidly growing seems to be 'supergravity', in which gravity is related to a spin-3/2 field through a symmetry. This removes some divergences, has positive energy, and, as shown by R. Tabensky and C. Teitelboim (Princeton University), can be regarded as a 'square-root' of general relativity much as Dirac's equation is related to the Klein-Gordon equation. S. W. Hawking (University of Cambridge), speaking on path-integral formulations, pictured the vacuum as a sea of Planck mass black holes and warned 'Danger! Virtual black holes.' The gap between quantum and classical approaches was still apparent, as when S. Weinberg (Massachusetts Institute of Technology) told a questioner that geometry did not matter, and only belatedly added 'in this case'.

One interesting contribution that did not materialise was by L. Domash (Maharishi University) on levitation. Did his theory break down in mid-Atlantic? Anyway, only lesser adepts in meditation were present. □

Oocyte microinjection

from H. Chantrenne

A symposium on the use of *Xenopus* oocytes in the study of DNA transcription and mRNA translation was held on 16 July, 1977 at the Université Libre de Bruxelles as part of an EMBO course. It was organised by Dr G. Marbaix and Dr G. Huez, Laboratoire de Chimie Biologique, Département de Biologie Moléculaire, Université Libre de Bruxelles.

THE colloquium presented some recent results obtained with *Xenopus* oocytes. J. Brachet (Brussels) provided an introduction to oocyte structure and oogenesis.

A novel development is the use of oocytes to study the expression of injected DNA. J. B. Gurdon (MRC Laboratory of Molecular Biology, Cambridge) described techniques he has developed for studying the expression of purified genes by injecting the DNA into the oocyte germinal vesicle, where

it is transcribed. He also described recent experiments showing that the oocyte cytoplasm can 'reprogram' injected nuclei. Nuclei from fully-differentiated *Xenopus* cells injected into oocytes of the newt *Pleurodeles*, directed the synthesis of proteins characteristic of the *Pleurodeles* oocyte stage rather than proteins characteristic of the differentiated cell (see *Proc. natn. Acad. Sci. U.S.A.* **74**, 2470; 1977).

The oocyte provides an alternative to the more usual cell-free systems for studying the translation of mRNA. L. van Vloten-Doting (State University, Leiden) emphasised the advantage of the oocyte. Translation is correct, the oocyte is of course able to adjust the conditions for adequate operation of the complex protein-synthesising machinery, and translation continues for several days. Another remarkable feature is the oocyte's ability to bring about correct post-transcriptional modification of the newly-synthesised polypeptide.

An illustration of this was given by J. Ghysdael (Brussels) with the 35S RNA from avian myeloblastosis virus. When injected into oocytes this RNA directs the synthesis of a long polypeptide which is the precursor of the 'group antigens' of the virus. In the oocytes it is correctly split into four viral proteins (p27, p19, p15, p12) exactly as in infected chick fibroblasts, but much more slowly, allowing a clear analysis of the process by classical chasing methods. According to C. von der Helm (see *Proc. natn. Acad. Sci. U.S.A.* **74**, 911; 1977) protein p15, one of the final products of polypeptide cleavage, is involved in the cleavage. This raises an intriguing problem, for p15 is not initially present in the oocyte; no-one knows at present whether it can act enzymatically when it is still part of the large polypeptide and provided that the concentration of the latter is sufficient, or whether selective cleavage is brought about by oocyte enzymes.

G. Huez and G. Marbaix (Brussels) have been studying the role of poly(A) in the stability of the messenger. They showed that the addition of poly(A) to a histone mRNA lacking poly(A) increases its half-life in the oocyte from around 10 to more than 48 hours. G. Vassart (Brussels) showed how the translation of thyroglobulin mRNA in oocytes has resolved the controversy over the size of the protein subunit, which turns out to have a molecular weight of 300,000. It is only in the oocyte that this messenger is translated correctly. B. Lebleu (Brussels) showed that crude preparations of mRNA from cells induced to produce interferon directed the synthesis of biologically active interferon in the oocyte. □

H. Chantrenne is Professor of Biochemistry in the Faculty of Sciences, Université Libre de Bruxelles.

Ultraviolet spectrum of quasi-stellar object 3C273

Arthur F. Davidsen, George F. Hartig & William G. Fastie

Department of Physics, The Johns Hopkins University, Baltimore, Maryland 21218

The first direct observation of the ultraviolet spectrum of a quasi-stellar object (QSO) has been made with a rocket-borne telescope. The emission line spectrum of 3C273 is similar to the spectra of high-redshift QSOs, but no absorption is observed. The results provide important new constraints on theoretical models of QSOs, place a severe limit on the density of neutral hydrogen in the intergalactic medium, and suggest a cosmological origin for much of the absorption seen in high-redshift QSOs. Comparison of the ultraviolet spectrophotometry of low- and high-redshift QSOs suggests that the universe is closed, with $q_0 \sim 1$.

It has long been recognised that ultraviolet observations of low-redshift quasi-stellar objects (QSOs) made with space-borne telescopes might reveal important clues concerning the nature of these objects. Among the problems for which such observations are relevant are the nature of the energy source, the physical conditions in the emission line envelopes, and the origin of the absorption lines seen in high-redshift QSOs. It now seems that these observations may also be of great significance for cosmology. Here we report the first observation of the ultraviolet spectrum of a QSO, made with a telescope carried above the Earth's atmosphere by a sounding rocket. The spectrum of 3C273 is presented and some of its implications are briefly discussed. Further details of the observation and analysis will be described elsewhere¹.

Faint object telescope

The observation was made with a new instrument², which we call the Faint Object Telescope (FOT), designed especially for moderate resolution (10–15 Å) ultraviolet spectrophotometry of faint extragalactic objects in the wavelength region between 1,200 and 1,700 Å. The FOT uses a 40-cm diameter $f/15$ telescope, whose 1,100 cm² collecting area makes it the largest optical telescope ever flown in a sounding rocket. A spectrum is formed by a concave grating which gives a dispersion of 20 Å mm⁻¹ at the detector focal plane. The spectrograph has two circular entrance apertures whose diameters, projected on the sky, are 2.2 arc min with a centre-to-centre spacing of 4.4 arc min. One aperture observes the target while the other accumulates simultaneous background data.

The FOT detector consists of two 25-mm diameter micro-channel plates mounted in a chevron configuration, followed by two one-dimensional resistive anode readout devices^{3–5} for accumulating separate spectra of the target and background. The detector has a magnesium fluoride window, and a caesium iodide photocathode is deposited directly on the front surface of the first microchannel plate. Pressure in the detector is maintained below 10⁻⁷ torr by an ion pump which is turned

off before flight. The spectrum observed in the target channel is displayed on the ground in real time by a multichannel analyser.

The overall effective collecting area of the FOT varies between 11 and 5 cm² over the range 1,250–1,700 Å. Pre-flight and post-flight calibrations agree within the errors of less than 5%. The absolute calibration, obtained by comparison with measurements made with an NBS-calibrated photodiode, is accurate to about 10%. The instrumental resolution is about 10 Å over most of the spectrum and degrades to about 15 Å at the shortest wavelengths.

A unique rocket pointing system has been developed for the FOT by the Sounding Rocket Division of NASA's Goddard Space Flight Center. Two star-trackers are mounted behind the telescope primary, with adjustable mirrors which enable them to view out through the side of the rocket. These star-trackers lock on to two bright stars which are chosen to be nearly orthogonal to the target direction and to each other. Signals from one tracker control yaw and roll jets in the attitude control system, while the second tracker controls pitch. With accurate alignment of the trackers and telescope, pointing within 1 arc min to any target can be accomplished.

In addition to this system, the FOT utilises an SIT vidicon television camera which is focused on the mirrored entrance plate of the spectrograph. Television pictures of a 15-arc min field surrounding the target and background apertures are transmitted to the ground, where the experimenter can verify the pointing of the telescope by reference to stars as faint as 10 mag. A remote command system can then be used to make fine adjustments to the pointing. The operation of the FOT is, therefore, somewhat similar to the operation of large ground-based telescopes.

Launch and data

The Faint Object Telescope was launched aboard a NASA Black Brant VC sounding rocket from White Sands Missile Range on 16 April 1977 at 0500 UT. The star-trackers acquired Vega and Capella and pointed the FOT so that 3C273 was within 50 arc s of the centre of the target aperture. A series of commands were then sent to centre the target in the spectrograph aperture. Pointing was automatically maintained throughout the rest of the flight with a total jitter of about ± 15 arc s. The payload reached a peak altitude of 218 km and obtained a total of 270 s of data at altitudes above 130 km.

Some 13,000 photons were detected from 3C273 during a 235-s observation after the target was centred in the spectrograph entrance aperture. The total background correction was $\sim 2,000$ counts, determined from simultaneous observations through the sky aperture as well as observations made with the target aperture before and after the 3C273 observation. About half of the background was due to dark counts distributed nearly uniformly over the whole spectrum. The other half was due to geocoronal Lyman α emission, for which the FOT has

Fig. 1 The ultraviolet spectrum of the QSO 3C273. The strongest emission line is hydrogen Lyman α λ 1,216 with a redshift $z = 0.16$. The asymmetry of the line is attributed to N(v) λ 1,240 emission. The broad feature at λ_{rest} 1,400 Å is similar to that usually attributed to Si (iv) and O (iv) in high-redshift QSOs. There are also probable emission features which may be due to O (i) λ 1,304 and Si (ii) λ 1,265. The continuum is flat, with no evidence of strong absorption shortward of Lyman α .

a small residual sensitivity at detector positions corresponding to wavelengths shorter than 1,300 Å. The background corrected spectrum was smoothed with a sliding average of 3 wavelength bins (7.7 Å) to reduce the effects of slightly uneven bin widths in the analog-to-digital converter. The count-rate data were then reduced to absolute flux units by dividing by the response function of the FOT.

Emission line spectrum

The ultraviolet spectrum of 3C273 is shown in Fig. 1. As in the case of very high-redshift QSOs, the strongest emission feature is Lyman α . Its redshift, $z = 0.16$, is the same as the value obtained originally from the Balmer lines⁶. In addition there are emission features due to N(v) λ 1,240 (blended with L α), Si(iv) and O(iv) λ 1,400, and O(i) λ 1,304. There are also possible emission features at λ 1,265 and λ 1,286. The first of these can plausibly be identified with Si(ii). The equivalent width of the L α + N(v) feature is 67 Å in the rest frame. We estimate from the asymmetry of the feature that one quarter of this is due to N(v). The continuum is flat, with a flux of $9.5 \pm 1.0 \times 10^{-26}$ erg cm⁻² s⁻¹ Hz⁻¹. The flux in L α is, therefore, about 9×10^{-12} erg cm⁻² s⁻¹. Better estimates of the emission line intensities and their widths will be available when we have had the opportunity to compare the data with the results of synthetic FOT spectra (see ref. 1).

Several attempts to reproduce QSO emission line spectra have been made, using a model consisting of a power-law source of ionising radiation surrounded by clouds or filaments of gas⁷⁻¹⁰. Until now, however, there have been no observations of a single QSO covering both the ultraviolet and the optical emission lines. Theorists have had to resort to a 'composite QSO spectrum' pieced together from observations of different rest-wavelengths in many QSOs of varying redshifts. The usual assumption for normalising the ultraviolet and optical data has been to take the flux ratio $F(\text{L}\alpha)/F(\text{H}\beta) = 40$, corresponding to production of these lines primarily by radiative recombination, but with some enhancement of L α due to collisional excitation. Combining our measurement of the L α flux with the previously measured H β flux¹¹, we find $F(\text{L}\alpha)/F(\text{H}\beta) \approx 4$ in 3C273, an order of magnitude smaller than the canonical value. A similar result has been obtained in a very careful composite QSO study¹².

This remarkable departure of the observed Lyman/Balmer ratio from the expected one is likely to have a major impact on QSO models. The most obvious explanation, that the ultraviolet lines are attenuated by absorption by dust similar to that observed in the interstellar medium, seems untenable in view of observations of Paschen α that indicate the hydrogen lines are unreddened¹³. But, dust which is distributed within the line-emitting gas might destroy L α without having much effect on the Balmer and Paschen lines if the nebula has high optical depth to L α photons. An additional mechanism which might play a part in depleting L α in an optically thick nebula is photo-ionisation of He 2³S by trapped L α photons¹⁴. Some alternatives have been mentioned by Baldwin¹². Whatever mechanism is at work, an understanding of the reduced L α /H β ratio may lead to vastly improved knowledge of the physical conditions in QSO envelopes.

Non-thermal continuum

It is usually assumed that the optical continuum observed in QSOs and active galactic nuclei can be extrapolated to the far-ultraviolet with a power-law $F_{\nu} \propto \nu^{-\alpha}$ to provide the photo-ionising flux needed to explain the emission lines. Theoretical models of this type are sensitive to the flux at the Lyman limit as well as the spectral index α . This observation of 3C273 makes it the first QSO for which the continuum flux is well-determined over a broad wavelength range.

In Fig. 2 we have collected spectral data on 3C273 extending from the infrared to the far-ultraviolet. The data at 2 μ m are from Grasdalen¹³, the optical data are from Oke and Shields¹⁵, the near ultraviolet data are recent broad band measurements by the ANS satellite¹⁶, and the far-ultraviolet data are the measurements reported here. Two of the ANS bands fall at the expected wavelengths of the C(iv) λ 1,550 and C(III) λ 1,909 lines, which are normally strong in high-redshift QSOs.

From Pa to Ha the spectral index is $\alpha = 1.0$, but between Ha and L α the spectrum is flatter, with $\alpha = 0.6$. In addition there is a broad hump centred at $\sim 3,500$ Å. Such a feature has been noted in several QSOs by Baldwin¹¹, who has interpreted it as Balmer continuum emission. It is evident that the spectrum of 3C273 cannot be described by a single power-law, but because only a very small extrapolation is now required, the flux at the Lyman limit is reasonably well-determined. We estimate F_{ν} (Lyman limit) = 8×10^{-26} erg cm⁻² s⁻¹ Hz⁻¹, with an uncertainty of about 20%. This corresponds to a continuum luminosity $L_{\nu} = 7 \times 10^{30}$ erg cm⁻² s⁻¹ Hz⁻¹, assuming $H_0 = 50$ km s⁻¹ Mpc⁻¹ and $q_0 = +1$. The spectral index just below the Lyman limit is $0 \lesssim \alpha \lesssim 0.6$, but α must increase ($\alpha \gtrsim 1.2$) somewhere above the limit to agree with the X-ray observations¹⁷.

Fig. 2 The spectrum of 3C273 from the near-infrared to the far-ultraviolet. Infrared data¹³ are represented by a curve. Optical data are shown as measured fluxes and assumed continuum¹⁵. Five broad-band ultraviolet measurements by the ANS satellite¹⁶ are shown as squares, with dashed lines to indicate assumed continuum and lines. The far-ultraviolet data from Fig. 1 are also shown.

No corrections for reddening have been made to any of the data shown in Fig. 2. The chief evidence against reddening of the overall spectrum is the Pa/H β measurement¹³, which agrees with recombination theory. Galactic reddening is expected to be small or zero¹⁸ at the high galactic latitude ($b^{\text{II}} = 64^\circ$) of 3C273. An estimate based on the 21-cm hydrogen column density¹⁹ and the relation between N_{H} and reddening^{20, 21} gives $E_{\text{B-V}}$ (galactic) = 0.01, which would give extinction of 0.1 mag at Lyman α using the OAO extinction curve²².

Intergalactic matter

The absence of absorption shortward of the red-shifted La emission is another important result of this observation. Gunn and Peterson²³ showed that neutral hydrogen distributed smoothly in the intergalactic medium should produce an absorption trough extending from 1,216 Å to 1,216 (1+z) Å in the spectrum of a QSO, assuming its redshift is cosmological. The optical depth in the trough at a wavelength corresponding to redshift z is²⁴

$$\tau = 1.7 \times 10^{11} \frac{n_{\text{H}}(z)}{(1+z)^{3/2}}$$

in a Friedmann model universe with the critical density parameter $\Omega = 1$. Since no trough is observed in the 3C273 spectrum, we take $\tau < 0.2$ and find the upper limit

$$n_{\text{H}} < 1.5 \times 10^{-12} \text{ cm}^{-3}$$

for $z \sim 0.07$ –0.15. The contribution to the critical density due to neutral hydrogen is, therefore, $\Omega_{\text{H}} < 5 \times 10^{-7}$ at $z \simeq 0.1$. This is by far the strongest limit on neutral hydrogen in the intergalactic medium at a recent epoch, but a similar limit has previously been obtained at $z \simeq 2$ from observations of high-redshift QSOs (see ref. 25 for a review). These results indicate that if there is any intergalactic gas it has remained highly ionised over most of the history of the Universe.

QSO absorption lines

Absorption lines have been seen in the spectra of many high-redshift QSOs and most of these are found shortward of the La emission line²⁵. It is highly controversial whether all of these lines arise in material associated with the QSOs, or whether some of the absorption is produced in intervening clouds or galaxies. On the intervening matter hypothesis, the absorption should be absent in low-redshift QSOs²⁶.

Absorption lines are not readily detectable at the modest resolution of the present observations of 3C273. It is still possible to make an interesting comparison between 3C273 and high-redshift QSOs, however, because even at low resolution, these objects usually show a marked depression of the apparent continuum shortward of La due to the blending of many absorption lines. For example 10 QSOs with $2.5 \leq z \leq 3.1$ have been well observed both longward and shortward of La by Osmer and Smith²⁷. For these objects we have estimated the ratio of the flux density in the wavelength range 1,120–1,180 Å to that at 1,475 Å (tabulated by Osmer and Smith). A wavelength region slightly longer than La was not chosen because of possible contamination by emission lines. The mean value of this ratio is 0.66, with a range from 0.51 to 0.81. Our observation of 3C273 yields 0.98 ± 0.06 for this ratio, and suggests that absorption lines will not be detected when high resolution observations of this object are eventually made. These results are, therefore, consistent with the hypothesis that much of the absorption seen in high-redshift QSOs is due to matter at smaller cosmological redshifts.

One difficulty with this comparison is that the high redshift objects are more luminous than 3C273 by a factor between 3 and 10, and there could conceivably be more absorption in higher luminosity objects if, for example, material is expelled by radiation pressure. A scan of OH 471 (Baldwin, J. A., personal communication), which has $z = 3.4$ and a continuum luminosity very similar to that of 3C273 for $q_0 = +1$, has,

Table 1 QSOs of similar luminosity

Object	z	AB_{V} (1,450 Å)	$\log W_{\lambda}$ (La + N(v))	$\log L_{\text{V}}$ (1,450 Å)
4C25.05	2.34	18.7 ± 0.2	1.84	30.93 ± 0.08
2256+017	2.66	19.3 ± 0.4	1.79	30.76 ± 0.16
4C05.34	2.86	18.3 ± 0.2	1.79	31.20 ± 0.08
0830+115	2.97	19.2 ± 0.2	1.87	30.86 ± 0.08
OH 471	3.39	19.1 ± 0.2	1.86	30.97 ± 0.08
Average	2.84	18.92 ± 0.37	1.83 ± 0.03	30.94 ± 0.15
3C273	0.158	13.96 ± 0.10	1.83 ± 0.04	30.94 ± 0.04

however, a continuum depression ratio of about 0.5, similar to that of the other high-redshift QSOs. Therefore, we tentatively conclude that the continuum depression ratio is correlated with redshift and that much of the absorption seen in high-redshift QSOs arises in matter at smaller, cosmological redshifts. It will be necessary to obtain further ultraviolet observations of intermediate-redshift QSOs, and eventually high resolution ultraviolet spectra, in order to confirm this conclusion.

Cosmology with QSOs

Quasars have been disappointing as cosmological probes, despite their high visibility at large redshifts, because if their redshifts are cosmological, they have a very large range of luminosities. It has recently been shown, however, that there is a good correlation between the continuum luminosity at a rest-wavelength of 1,450 Å, calculated under the assumption of cosmological redshifts, and the equivalent widths of the La+N(v) and C(IV) emission features in 20 high-redshift QSOs²⁸. Another study found a similar correlation with La (but not C(IV)) in 29 mostly radio-quiet QSOs²⁹. The relations are especially tight if the sample is restricted to only the flat spectrum radio sources²⁸, suggesting that these objects may be useful as standard candles.

In Table 1 we list the flat-spectrum radio QSOs from the study of Baldwin²⁸, which have equivalent widths W_{λ} (La+N(v)) within 10% of the value observed in 3C273. The continuum luminosities $L_{\text{V}}(1,450 \text{ Å})$ have been calculated under the assumption of cosmological redshifts with the Hubble constant $H_0 = 50 \text{ km s}^{-1} \text{ Mpc}^{-1}$ and the deceleration parameter $q_0 = +1$. Also listed are the apparent magnitudes $AB_{\text{V}}(1,450 \text{ Å})$ on

Fig. 3. A redshift-magnitude diagram for the QSOs in Table 1. Only flat-spectrum radio sources with $W_{\lambda}(\text{La} + \text{N(v)})$ similar to that of 3C273 are included. The circled point is the average of the five high-redshift objects. The curves show expected relationships for various values of the deceleration parameter q_0 in Friedmann model universes.

the Oke system ($AB_V = -2.5 \log F_V - 48.60$). The average of the five high-redshift QSOs has the same equivalent width as 3C273 and the same luminosity if $q_0 = +1$. These objects can, therefore, be compared directly in a redshift-magnitude diagram. The result is shown in Fig. 3.

Also shown in Fig. 3 are the expected redshift-magnitude relationships for various values of q_0 in Friedmann model universes with zero cosmological constant³⁰. These curves are arbitrarily normalised to go through the point representing 3C273. This comparison of high- and low-redshift QSOs thought to have similar intrinsic luminosities favours a value of $q_0 \approx +1$. If q_0 were greater than 0.5 it would indicate that the universe is closed.

There are two important cautionary notes in connection with this result. First, the reality of the equivalent widths of the ultraviolet emission lines as a luminosity indicator is not yet firmly established. This is because one also obtains a good correlation between apparent luminosity and equivalent width¹⁸. This remains true with the addition of 3C273 to the sample if one considers observed equivalent widths rather than rest-frame values. Ultraviolet observations of several low-redshift QSOs and Seyfert galaxies with a wide range of luminosities are needed to decide whether the luminosity-equivalent width relationship is real.

A second uncertainty in the present result for q_0 is the reddening of 3C273. In Fig. 3, 3C273 is plotted with no correction for reddening the Galaxy. If $E_{B-V} = 0.01$ as estimated above, the correction at 1,450 Å is less than 0.1 mag, which is small compared with other uncertainties. If, however $E_{B-V} = 0.06$, the ultra-violet magnitude should be brighter by about 0.5, which would give $q_0 \approx 0.5$. A larger reddening correction would reverse the evidence favouring a closed universe.

While it would be premature to conclude that the universe is closed, it is encouraging to think that QSOs may turn out to be useful cosmological probes. Further ultraviolet observations

may be expected to contribute to the solution of this problem, as well as to our understanding of QSOs and active galactic nuclei.

Future sea-level changes due to West Antarctic ice sheet fluctuations

J. A. Clark

Cooperative Institute for Research in Environmental Sciences and Institute of Arctic and Alpine Research, University of Colorado, Boulder, Colorado 80309

C. S. Lingle

Department of Geological Sciences, University of Maine at Orono, Orono, Maine 04473

Global sea-level changes which would result from an instantaneous uniform thinning of the possibly unstable West Antarctic ice sheet are calculated and found to be non-uniform. At locations distant from the ice sheet (Hawaii, New York, the North Sea), immediate submergence would be followed by gradual emergence. At New Zealand, immediate submergence would be followed by gradual additional submergence, then slow emergence would begin after 2,500 yr. At locations close to the ice sheet (Cape Horn, the Ross Ice Shelf), the sea level would fall for 1,100 yr. then rapid submergence would start resulting in a net sea-level rise after 10,000 yr equal to about 92% of the average global rise.

It is commonly believed that the rise in sea level due to a glacial melting episode is uniform everywhere. That is, the observed sea-level rise, S , due to the melting of a mass of ice M_i is $S = M_i / \rho_w A$ with ρ_w the density of water and A the area of the oceans. This is

wrong because the ocean floor deforms under the weight of the changing ice and water loads and the ocean surface (the geoid) distorts as mass is redistributed on the surface, as well as within, the Earth. The observed change in sea level is the change in separation between the geoid and the ocean floor and Farrell and Clark¹ show that, when glaciers melt, the change in separation between these dynamic surfaces is not constant. We use their method in this analysis to predict changes in sea level which would result from melting (or accretion) of a uniform amount of ice from the relatively unstable West Antarctic ice sheet.

Instability in the West Antarctic ice sheet

The West Antarctic ice sheet (WIS), that portion of the Antarctic ice sheet lying in the Western Hemisphere and mostly east of the Transantarctic Mountains, was shown to be grounded extensively below sea level by seismic studies completed before 1961 (ref. 2). Weertman³ has shown that such marine ice sheets are not inherently stable, and Hughes⁴ has discussed several lines of evidence which indicate that WIS has disintegrated extensively

Fig. 1 The marine portion of the West Antarctic ice sheet (WIS) lies in the Western Hemisphere east of the Transantarctic Mountains. It is approximated for purposes of the numerical calculation by the area within the dashed line. The global sea-level changes which would result from a uniform thinning of the ice within this area are calculated.

since 10,000 yr BP, and has suggested that the process may be continuing.

Denton and Borns⁵ found that grounding of WIS in the vicinity of McMurdo Sound occurred before 47,000 yr BP. Following expansion, WIS remained grounded to the edge of the continental shelf until about 18,000 BP (ref. 5) (G. H. Denton, private communication) and then began retreating. WIS ungrounded once again in the McMurdo area by 6,000 yr BP (ref. 6). Thomas⁷ also suggests that accumulation rates near the West Antarctic ice divide imply continuous thickening of the WIS interior until 2,000 yr BP when thinning started, possibly as a delayed response to retreat of the grounding line.

Recent survey measurements made by Thomas⁷ on the Ross Ice Shelf indicate that part of the WIS grounding line may be advancing. If this is the case, the disintegration may be reversing, and WIS may now be expanding. The apparent inability of WIS to attain a state of equilibrium accords with the theory³ that predicts a marine ice sheet will be stable only after advancing to the edge of a continental shelf, or until water at the margin reaches a critical depth.

The model

The Earth is assumed to be a spherically symmetric, layered, self-gravitating, Maxwell viscoelastic solid. The elastic structure is that of a Gutenberg–Bullen Earth model with a uniform mantle viscosity of 10^{22} P and an inviscid core. Such a model has been suggested by others^{9,10} to closely approximate the real Earth.

The procedure, thoroughly described by Farrell and Clark¹ uses a Green function, $G(r-r_0, t-\tau)$, calculated by Peltier⁸ for the above Earth model. This Green function gives the effect of a 1-kg point load placed on the Earth's surface at position r and time τ upon relative sea level s at some other position r_0 and some later time t . To determine the relative sea-level change resulting from a distributed load that varies through time, consider the load to be a collection of point loads and add the effects of each. The relative sea-level change is then

$$s(r_0, t) = \int_{-\infty}^t \left(\iint_{\text{Load}} G(r-r_0, t-\tau) L(r, \tau) dr \right) d\tau \quad (1)$$

with L the surface load function. The load is comprised of a water load (L_w), and an ice load (L_i) so that

$$L = L_w + L_i = \rho_w s + \rho_i I \quad (2)$$

with ρ_w the density of water, ρ_i the density of ice, and I the ice thickness. Furthermore, the Green function can be separated into a time-independent elastic part (G_E) and a time-dependent viscous part (G_V)

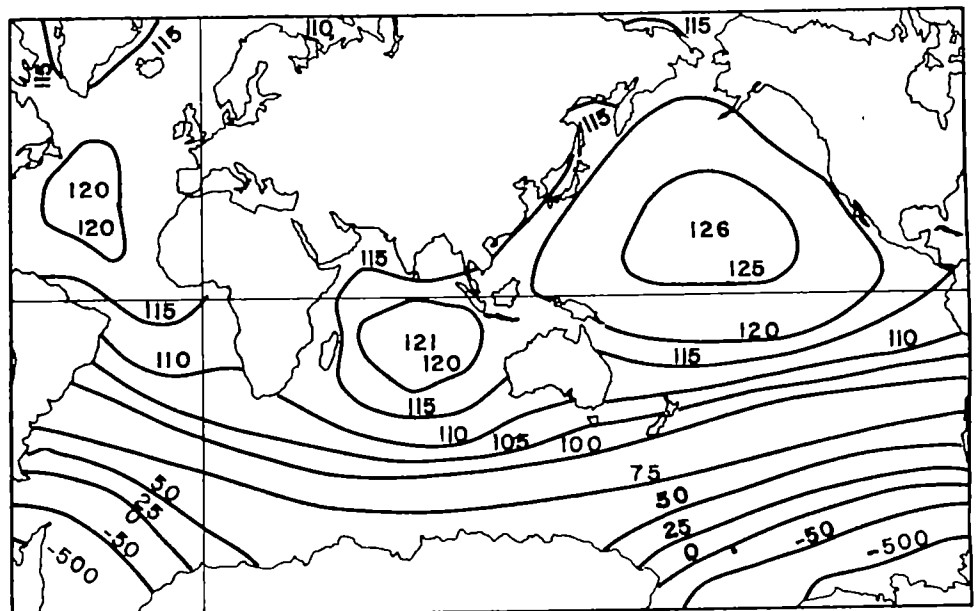

$$G = G_E + G_V \quad (3)$$

Substituting equations (2) and (3) into equation (1) gives

$$s(r_0, t) = \iint G_E(r-r_0) \rho_w s(r, t) dr + \iint_{\text{Ice}} G_E(r-r_0) \rho_i I(r, t) dr + \int_{-\infty}^t \left(\iint_{\text{Load}} G_V(r-r_0, t-\tau) L(r, \tau) d\tau \right) d\tau \quad (4)$$

The last term in equation (4) describes the time dependent viscous response of the Earth (the 'isostatic' response) to past ice and water load changes and the second term accounts for the immediate elastic response of the Earth to changing ice loads. The first term in equation (4) describes the Earth's elastic response to water load changes. Because s appears on both sides of equation (4), it is an integral equation describing a feedback process where meltwater

Fig. 2 Sea level changes everywhere immediately after a uniform thinning of WIS are shown as per cent of average global sea level rise (volume of water added to ocean-ocean area). The non-uniform distribution of sea level change is caused by the Earth's immediate elastic response to changed ice and water loading, plus the change in gravitational attraction exerted by WIS on the surrounding ocean. (The 100% contour corresponds to the 0.69 cm average oceanwide rise which would result from uniform thinning of WIS by 1 m.)

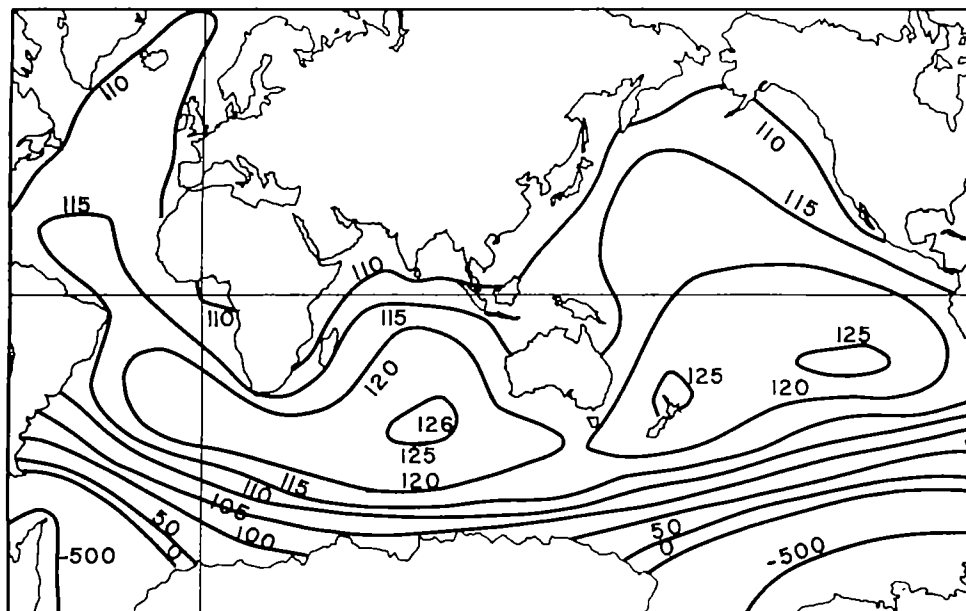

Fig. 3 Sea level changes everywhere 1,000 yr after the assumed uniform thinning of WIS, again shown as a percentage of average oceanwide rise. The new distribution of values results from gradual flow of material within the Earth's mantle.

deforms the Earth and then flows to fill the resulting depressions in the ocean surface. This changes the water load and the process is repeated until equilibrium is attained. Equation (4) can be solved numerically, with realistic ice and ocean configurations, for the relative sea level change at any location and at any time.

The ice thinning model is a simple one in which 1 m of ice is uniformly removed from the entire WIS (see Fig. 1). The oceanwide average sea level rise, S , is then 0.69 cm. The rheological model is linear and so a doubling, for instance, of our assumed amount of uniform thinning results in a doubling of the predicted sea level changes everywhere. Furthermore, if WIS should thicken by 1 m instead of thinning, the predicted sea level changes would be identical in magnitude but opposite in sign to those given below. Our results are, therefore, quite general.

Fig. 4 Sea level change against time at six selected locations, for 10,000 yr following the assumed uniform thinning of WIS. At New Zealand, immediate submergence nearly equal to the average global rise is followed by continued submergence for 2,500 yr. Slight emergence follows. 10,000 yr later, net submergence is 120% of average global rise. At Hawaii, New York and the North Sea, immediate submergence of 125% to 110% is followed by emergence of 15% to 13%. At Cape Horn and near the Ross Ice Shelf, the sea level actually falls by 8% and 40%, respectively. Emergence continues for about 1,200 yr, after which sea level begins to rise. After 10,000 yr, net submergence is about 92% of average global rise.

Results

The results are given as the changes in sea level which would be caused solely by thinning of WIS. Tectonic effects and effects due to changes in glaciers elsewhere are not included. All reported values are in per cent of S , the oceanwide average sea level change.

Figure 2 shows changes in sea level everywhere immediately after the ice has melted. On Hawaii, for example, sea level rises 125% of S ($1.25 \times 0.69 = 0.86$ cm for the 1 m thinning case), while near the Ross Ice Shelf, the negative values indicate that sea level actually falls by 40%. This fall in sea level occurs despite the fact that water was added to the ocean; it is caused by the combined effects of immediate elastic uplift of the ocean floor near the ice sheet¹¹ and reduced gravitational attraction of the ocean water by the ice mass^{12,13}. Only along the 100% contour does the observed sea level rise equal the oceanwide average rise, S .

After the Earth's immediate elastic response, viscous flow of material within the mantle slowly compensates for the new distribution of ice and water loads. Figure 3 shows the distribution of sea level changes (relative to present sea level) after 1,000 yr have elapsed. The sea level change at Hawaii is now only 116%, indicating that after the initial dramatic rise of 125% sea level slowly falls by 9%, resulting in slight emergence. In the extreme South Atlantic, however, where sea level rises only 50% initially (Fig. 2), Earth relaxation results in continual submergence so that after 1,000 yr sea level has risen to 100% of S . Figure 4 shows sea level change against time at six localities (New Zealand, Hawaii, New York, the North Sea, Cape Horn, and the Ross Ice Shelf) for 10,000 yr following the single ice-melting incident. For the North Sea, New York, and Hawaii, the sea level against time curves are similar in form, although slightly different in magnitude. Immediate submergence exceeding 100% of S is followed by slow emergence of only a few per cent of S . The predicted change in sea level on New Zealand is different because slow submergence, rather than emergence, occurs after the initial rapid rise of sea level. After 2,500 yr New Zealand also emerges slightly. Sea level falls at Cape Horn and the Ross Ice Shelf until 1,100 yr after the ice melting episode, then dramatic submergence occurs, drowning the present day beaches after 1,500 yr (at Cape Horn) and 3,400 yr (near the Ross Ice Shelf). Regions now under WIS will witness a continuing fall in sea level reaching magnitudes of up to -700% of S .

Conclusions

Sea level changes corresponding to future changes in the West Antarctic ice sheet will be affected by (1) changes in gravitational attraction exerted by the ice sheet on the surrounding ocean, (2) the

Earth's immediate elastic response to changed ice and water loads, and (3) the Earth's long-term response due to viscous flow within the mantle. If a uniform amount of ice was removed from WIS, the combined effect of these three processes would result in a non-uniform sea level change immediately afterwards ranging from +125% of the average global rise at Hawaii to -40% of the average rise near the Ross Ice Shelf, Antarctica.

Isotopic evidence for source of diagenetic carbonates formed during burial of organic-rich sediments

Hilary Irwin & Charles Curtis

Department of Geology, The University, Sheffield, UK

Max Coleman

Institute of Geological Sciences, Geochemical Division, 64-78 Gray's Inn Road, London, UK

Organic matter is modified by several processes operating at different depths during burial diagenesis: (1) sulphate reduction; (2) fermentation; (3) thermally-induced decarboxylation, and so on. CO₂, one common product of each, can be distinguished by its carbon isotope composition: approximately (1) -25‰, (2) +15‰, (3) -20‰ relative to PDB. These values are preserved in diagenetic carbonates of the Upper Jurassic Kimmeridge Clay. Independent corroboration of the relative dominance of each process within specific depth intervals is given by the isotopic composition of incorporated oxygen which is temperature dependent (1) 0 to -2‰, (2) -1.5 to -5‰, (3) -3.5 to -7.0‰.

A BELATED recognition of the potentially disastrous supply/demand situation for liquid hydrocarbons has reawakened interest in organic matter maturation processes in sediments. Much emphasis is placed on thermally-induced reactions but little on several other processes which equally affect source rock potential. These are more important at shallower burial depths and also lead to diagenetic cementation which can affect both hydrocarbon migration and reservoir properties.

Curtis recently¹ proposed that several different depth-related zones could be recognised within burial sequences and that kinetic controls (notably rate of burial) dictated the relative importance of each zone in determining the extent and style of diagenetic modification.

Figure 1 represents an order-of-magnitude model for depth zonation with particular reference to the generation of carbon dioxide. Note the nonlinear depth scale which exaggerates the depth span of shallower zones. Bacterial processes dominate in zones I, II and III. Carbon dioxide is one product of organic matter degradation in each with the following equations indicating the nature of each overall reaction:

The boundary between zones I and II is determined by the extent of downward diffusion of dissolved molecular oxygen from overlying waters and the lower limit of zone II by downward diffusion of sulphate (we shall here restrict the discussion to fairly rapidly deposited marine mudstones containing abundant organic matter and within which sulphate reduction almost invariably occurs). Fermentation starts as soon as sulphate reduction stops (possibly because the bacteria cannot tolerate dissolved sulphides) and presumably continues until prevented by either high temperatures or exhaustion of suitable organic substrate. The rate of production of carbon dioxide within each zone decreases with depth due to diminishing oxygen, sulphate and substrate quality respectively.

Zone IV is less clearly defined with respect to depth or process. One well documented reaction is decarboxylation:

The rate of this (and similar) abiotic reaction presumably increases with rising temperature and then slows as suitable molecules are exhausted. Oxidation by detrital ferric compounds also must cause organic matter degradation: in Fig. 1 this is depicted to be relatively important at shallow depths where pyrite forms from reactive soil sesquioxides and again at greater depths where higher temperatures promote reduction of less reactive detrital phases.

The carbon dioxide produced by all these reactions dissolves readily in porewater to increase bicarbonate concentrations. Its carbon isotopic composition, however, must be anticipated to be very different from that of marine reservoir bicarbonate (~ 0‰PDB) since the source in each case is organic matter (~ -25‰PDB). Bacterial oxidation and sulphate reduction seem to impose little fractionation such that very light bicarbonate is to be anticipated. There is some evidence² for believing that decarboxylation produces somewhat heavier (but still light) carbon dioxide. We have found no information relating to fractionation during oxidation by ferric compounds and have assumed that none occurs. Fermentation, however, imposes an extremely large fractionation³ with bacterial meth-

are values of -75‰_{PDB} commonplace⁴. Consequently, carbon dioxide produced in this reaction must be heavy and, in the absence of accurate information, we estimate something of the order of $+15\text{‰}$; certainly positive.

As sediments are buried, therefore, they pass successively through different zones within which organic matter is being altered and carbon dioxide produced. Bicarbonate activities sufficient to cause carbonate super-saturation are unlikely to be reached in zone I because of upward diffusion into depositional waters, but below this zone these levels are probable. The interesting feature is that carbonate precipitated from zone II should

be very light. There should then be a rapid and dramatic change to very heavy carbonates in zone III and then a less dramatic return to lighter values as fermentation becomes less important and decarboxylation more important into zone IV. It should be noted that unstable primary carbonates ($\delta^{13}\text{C} \sim 0\text{‰}_{\text{PDB}}$) might dissolve and add carbon of intermediate isotopic composition to the porewater reservoir in which case the above trends might be blurred.

Kimmeridge Clay

The onset of Kimmeridge Clay sedimentation marks a period of

marine transgression and water deepening over much of Western Europe. This has been linked with widespread tectonically-induced subsidence⁶. The sediments consist of uniform clays and shales, mostly organic rich, with occasional cementstones (dolomitic calcilitites) and siltstones. The Dorset Coast section is some 500 m thick and reflects a relatively deep basinal area within widespread epicontinental seas. The section is generally organic rich and a few horizons have been mined as oil shales. The Kimmeridge Clay is widely believed to be the principle source rock for North Sea oil.

Cementstone horizons of great lateral persistence are common in the Dorset Coast section, especially in its lower part. Many of these have been given local names⁶ which are included in Table 1, column 1. Discrete diagenetic carbonate nodules also occur and these too were sampled. In the upper part of the succession a third distinctive carbonate sediment is found as bands of impure (organic-rich) chalk, referred to as 'coccolithic limestones'. In all, 57 carbonate-rich samples were taken. Sample numbers (Table 1, column 2) reflect relative position within the sequence.

This sequence is entirely marine, relatively rapidly deposited, organic rich and contains much carbonate, some of which is undoubtedly of diagenetic origin. It also is sulphur rich (diagenetic pyrite and sulphur in organic compounds). It therefore should be a good place to test the reality of the zonal model outlined in Fig. 1.

Experimental procedures

Thin sections (very thin in the case of particularly fine-grained rocks) were prepared from each carbonate sample and 20–50 g crushed for analysis. Chemical (after Pearson⁷) and X-ray diffraction data were obtained for most samples and these results will be discussed in detail elsewhere.

The vast majority of samples fall into just three classes. The cementstones consist mostly of fine-grained mosaics of interlocking crystals euhedral to subhedral in outline. The carbonate phase ranges in composition between $(\text{Ca}_{0.848} \text{Mg}_{0.338} \text{Fe}_{0.117})\text{CO}_3$ and $(\text{Ca}_{0.554} \text{Mg}_{0.385} \text{Fe}_{0.062})\text{CO}_3$. Strictly, the iron-rich samples are ankerites, and the iron-poor samples ferroan dolomites. d_{104} varies between 2.898 Å and 2.909 Å. For simplicity this phase will be referred to as dolomite below.

The coccolithic limestones are all fairly pure calcites, ranging between $(\text{Ca}_{0.979} \text{Mg}_{0.002} \text{Fe}_{0.020})\text{CO}_3$ and $(\text{Ca}_{0.989} \text{Mg}_{0.004} \text{Fe}_{0.007})\text{CO}_3$ with d_{104} between 3.032 Å and 3.035 Å. In thin section, elongated lenses of coccoliths are separated by organic-rich laminae. Bioturbation and small scale cross lamination (ripples?) are not uncommon.

The nodules consist of fine-grained microsparite calcite (d_{104} 3.0206 Å to 3.0213 Å). Considerable Mg^{2+} and/or Fe^{2+} substitution is indicated. Pyrite is common in the Blackstone nodules which also show late calcite veins (817 V). Rotunda nodules often enclose ammonites.

For isotopic analysis, carbonate powder samples were washed with 1% sodium hypochlorite solution⁸ to remove organic compounds which can interfere with accurate isotope ratio determinations⁹. Carbon dioxide was prepared from about 10 mg of the treated sample by reaction with 100% phosphoric acid at 25.0 °C using a method similar to that described by McCrea¹⁰. Pure calcite samples had reacted completely in 2 h whereas dolomites required about 36 h.

Carbon dioxide was analysed with a Micromass 602-C mass spectrometer and the raw data corrected using the methods of Craig¹¹ and Deines¹². All samples were analysed with reference to carbon dioxide from a calcite standard prepared at the same time. Consequently, oxygen isotope ratios for dolomites were recalculated to compensate for a different fractionation factor for acid decomposition (assumed to be that for pure dolomite, 1.01110, ref. 13). The appropriate factor for calcite is 1.01025. Data for both oxygen and carbon are presented in the normal δ notation with reference to PDB standard in Table 1, columns 3 and 4.

Fig. 1 Introduction of diagenetic CO_2 within different diagenetic zones.

The oxygen isotopic equilibrium fractionation between a carbonate and water is a function of temperature. For calcite the relationship is given by

$$T = 16.9 - 4.21 (\delta_c - \delta_w) + 0.14 (\delta_c - \delta_w)^2$$

(ref. 14) where $(\delta_c - \delta_w)$ is the measured difference in $\delta^{18}\text{O}$ between calcite and water and is used here in the same sense as originally defined by Epstein *et al.*¹⁵. But there is much controversy about the precise extent of the fractionation between dolomite and water. The extrapolation of high temperature experimental data^{16,17} to 25 °C suggests that dolomite should be 5–7‰ heavier than coexisting calcite. This contrasts with some measurements which show that coexisting sedimentary dolomites and calcites have similar isotopic values^{18,19}. Low temperature experimental precipitation of protodolomite¹⁹ shows that it should be approximately 3‰ heavier than coexisting calcite. This value is intermediate between other estimates and can be considered to correspond reasonably to the probable conditions of precipitation of Kimmeridge dolomites. The expression given below is calculated from the original data

$$T = 31.9 - 5.55 (\delta_d - \delta_w) + 0.17 (\delta_d - \delta_w)^2$$

No account has been taken of possible slight isotopic fractionations due to iron substitution in the dolomite lattice.

An isotopic composition of -1.20‰ , the value for pre-glacial oceans (Shackleton and Kennett²⁰) has been assumed for both seawater and porewater. The isotopic equilibrium temperature, T , for each sample is listed in Table 1, column 5.

Discussion

Figure 2 is a plot of $\delta^{18}\text{O}_{\text{PDB}}$ against $\delta^{13}\text{C}_{\text{PDB}}$. Two precipitation temperature scales are given, one for calcite and one for dolomite (cementstones). The isotopic composition of the coccolith limestones is very much that to be expected for precipitation from marine reservoir bicarbonate in warm

Fig. 2 Plot of oxygen isotope ratio against carbon isotope ratio for all samples. Triangles represent diagenetic calcites, squares diagenetic dolomites and circles coccolithic calcites. The two temperature scales relate to different fractionations of dolomite and calcite with water of $\delta^{18}\text{O} = -1.2\text{‰}$.

surface waters ($\delta^{13}\text{C} \sim \text{zero}$, $\delta^{18}\text{O} \sim -3.3\text{‰}$ corresponding to approximately 26°C). Bearing in mind that some of the samples contain minor diagenetic carbonate, the range is small.

The nodular calcites show very different isotope ratios with $\delta^{13}\text{C} \sim -16\text{‰}$ and $\delta^{18}\text{O} \sim -0.8\text{‰}$ corresponding to a much lower precipitation temperature $T \sim 15^\circ\text{C}$ (exception sample 817B). These values lie well outside the range of all other samples. It seems reasonable to suggest that they precipitated not far below the sediment/water interface largely from carbon dioxide produced by sulphate-reducing bacteria (zone II, Fig. 1). The involvement of these bacteria during concretion development has been discussed by Raiswell²¹. The thermal gradient within marine depositional waters is in the reverse direction to that within buried sediments: the sediment/water interface must lie close to the temperature minimum within the total water plus sediment column. The presence of pyrite in these samples has already been noted.

The cementstones are remarkable for their wide range of both carbon and oxygen isotopic ratios. Carbon ranges from very heavy to light and oxygen isotope ratios indicate precipitation temperatures from 34°C to 66°C . Most remarkable of all is the very strong correlation between the two sets of data: heaviest carbonates being precipitated at the lowest temperatures. The obvious first interpretation is that these carbonates started to precipitate at some depth below the sediment/water interface from porewaters supersaturated with ^{13}C -rich bicarbonate and that precipitation continued to much greater burial depths where porewater bicarbonate was very much poorer in ^{13}C , in fact enriched in ^{12}C relative to marine reservoir bicarbonate. All these data can be matched easily with the zonal model in Fig. 1. The lower temperature dolomite samples precipitated near the top of zone III where fermentation processes introduced ^{13}C -rich bicarbonate from organic matter. The gradual and systematic changeover to ^{12}C -rich carbonates with depth of precipitation reflects the increasing importance of abiotic oxidation and decarboxylation reactions relative to fermentation downwards through zone III into zone IV. Although some cementstones contain minor calcite and it is possible that some primary calcite dissolved to contribute bicarbonate to the porewater pool, the observed trend is so well developed that we are forced to conclude that bicarbonate derived from organic matter was the principle source for both cementstones and nodular calcites.

From this discussion we feel that the isotope data obtained strongly support the view that distinctive depth-related zones of diagenesis, as shown in Fig. 1, persisted within the sediment column during Kimmeridge times. This work underlines the importance of diagenetic reactions being responsible for

significant modification of organic matter and the production of massive amounts of carbonate cement. There remains the intriguing and possibly important prospect of being able to determine the depth of precipitation assuming a particular thermal gradient.

The precipitation temperature data (Table 1, column 5 with the exception of Sample 817B) indicate a considerable break between zones II and III. For a thermal gradient of about 30°C per km this implies that bacterial fermentation first becomes important at depths of the order of 700 m. This is at variance with the proposition that the onset of fermentation is simply precluded by the activities of sulphate-reducing bacteria. There are, however, at least two reasons for doubting the reality of this large break between zones II and III.

As mentioned above, there is some uncertainty in the calibration of dolomite/water fractionation as a function of temperature (especially as the effect of iron substitution is unknown). If, for example, the value for dolomite were the same as that for calcite, as suggested by some evidence^{18,19} then the break would not exist. Using experimentally-derived calibrations^{16,17} would, of course, increase its magnitude. We do not think, however, that calibration uncertainties alone could account for the scale of the temperature/depth break.

There is a more compelling argument for doubting the reality of the break which also reconciles experimental and geological evidence. The major isotopic effect of diagenesis on porewater is depletion of ^{18}O associated with formation of diagenetic minerals enriched in that isotope. This applies to clay minerals as well as carbonates. The main accompanying physical effect is reduction of pore space and upward expression of water. At depth one would expect diagenetic minerals to be formed in equilibrium with isotopically light modified connate water. Measurements on porewater in samples recovered from the Deep Sea Drilling Project^{22,23} show a systematic reduction of $\delta^{18}\text{O}$ with depth to a maximum of 3‰ at 300 m. This was attributed to diagenetic reactions. This depletion should prevail at all depths below a mixing zone open to the effectively infinite seawater reservoir. The Kimmeridge sediments were probably deposited much more rapidly than those referred to above such that the 'mixing zone' was relatively limited in extent and effective for a shorter time with respect to any individual sediment unit. It should be noted that enrichment of ^{18}O in formation waters by exchange with isotopically heavy rocks²⁴ is a quite different effect from that produced by precipitation of diagenetic minerals.

A useful if very simple model which incorporates these effects can be constructed if certain assumptions are allowed. The downward limit of sulphate reduction is controlled by diffusion (see above): this limit thus crudely approximates to the boundary between open access to depositional water above and a closed system below. If we assume that the lowest temperature (shallowest) dolomite sample (No. 648) formed immediately below the sulphate reduction zone, then it would have precipitated at a similar temperature to nodular calcite (average 15.6°C). The $\delta^{18}\text{O}$ value of water in equilibrium with dolomite at this temperature is -4.9‰ . This figure can be thought of as the net depletion, caused by diagenetic processes in the burial column. To simplify the calculation we assume that the expressed water maintained this value throughout the uppermost 1 km of the sediment column and then changed abruptly to -1.2‰ at the sulphate-reduction zone.

Precipitation temperatures for the deeper diagenetic carbonates were calculated on this basis. These values, T_d , are given in Table 1, column 6. This approach, of course, is a gross oversimplification since there will be variation in $\delta^{18}\text{O}$ with depth below the mixing zone boundary. It nevertheless represents a reasonable first approximation. By assuming the temperature of the base of the sulphate-reduction zone is 15.6°C , its depth to be 10 m and a thermal gradient of 28°C per km (a value used in ref. 1), precipitation depths can be calculated and these are listed in Table 1, column 7. In Fig. 3, the various carbonate samples are plotted as $\delta^{13}\text{C}$ against precipitation temperature:

Fig. 3 Plot of calculated precipitation temperatures for Kimmeridge carbonates against carbon isotope ratio. 'Primary' carbonates are shown associated with depositional waters, diagenetic carbonates with sediment porewaters. Precipitation pathway is indicated showing passage through zone II (sulphate reduction) to zone III (fermentation-heavy C) to zone IV at the base where light carbon isotope ratios are again encountered. For discussion of porewater isotope composition and precipitation depth estimates see text. Symbols as for Fig. 2.

T for calcites, T_d for dolomites. Coccolithic limestone samples are plotted separately since they formed within the depositional environment.

Estimates of burial depths for precipitation of diagenetic dolomites suggest values ranging to 1 km. This means that all these carbonates precipitated relatively early during diagenesis and almost certainly predated liquid hydrocarbon formation or migration. The trend depicted in Fig. 3 represents a time

sequence for precipitation of carbonates at any particular sediment horizon. Carbonates precipitated from depositional waters obviously constitute the first component. Shortly after burial sulphate reduction may promote precipitation of early diagenetic carbonate, very rich in ^{12}C and reflecting low temperatures. The next carbonates to form will do so at similar temperatures but will have extremely different carbon isotope ratios with ^{13}C enrichment in consequence of fermentation reactions. Thereafter, successively later carbonates will reflect higher precipitation temperatures and the increasing influence of abiotic and decarboxylation reactions (^{12}C -rich bicarbonate input).

Work in hand involves extension of the investigation to later (deeper) precipitated carbonates in sandstones as well as in mudstone sequences. It is hoped to improve the calibration of depth/temperature scales as better models and new data become available.

We thank Professor C. Downie for help and advice, and Dr J. D. Hudson (Leicester University) for constructive criticism. Isotopic measurements were made in the Institute of Geological Sciences. The Natural Environment Research Council is supporting this work through a Research Studentship (H.L.) and Research Grant GR3-3086 (C.D.C.).

X-ray structures of two oxidation states of a flavin-nicotinamide biscoenzyme and models for flavin—nicotinamide interactions

David J. T. Porter* & Harold J. Bright

Department of Biochemistry and Biophysics, University of Pennsylvania, Philadelphia, Pennsylvania 19104

Donald Voet†

Department of Chemistry and Laboratory for Research on the Structure of Matter, University of Pennsylvania, Philadelphia, Pennsylvania 19104

The flavin nicotinamide biscoenzymes $\text{Fl}_{\text{ox}}^- - \text{C}_3 - \text{Nic}^+$ and $\text{H}_2\text{Fl}_{\text{red}} - \text{C}_3 - \text{Nic}^+$ assume extended conformations in the solid state. In both derivatives the nicotinamide and flavin groups associate through hydrogen bonding. The bending angle of the reduced flavin moiety is less than half that in any previously reported 1,5-dihydroflavin structure. This effect is apparently due to ring stacking interactions.

REDUCTION of a flavoenzyme by NADH is the primary step in many important biological oxidoreduction processes. Interactions between flavin and nicotinamide species of differing oxidation states have been described in several such flavoenzyme catalysed

*Present address: Novo Laboratories, 59 Danbury Road, Wilton, Connecticut.

†To whom correspondence should be addressed.

reactions¹. Complexes composed of reduced flavin and oxidised nicotinamide have been characterised as charge-transfer complexes by spectral criteria² as well as by the correlation of the energies of their long wavelength absorptions with the calculated lowest vacant orbital energies of their nicotinamide components³. Similarly, kinetic and spectral data have indicated that a kinetically important charge-transfer complex between reduced nicotinamide and oxidised flavin occurs before the reduction of flavins⁴⁻⁸. The geometry of this complex has been proposed to be one in which the two ring systems are face-to-face such that the nicotinamide C(4) atom is opposite the flavin N(5) atom⁵. Flavin-nicotinamide oxidoreduction is then postulated to occur by hydride ion transfer from the nicotinamide C(4) position to the flavin N(5) position⁵. Alternately, it has been proposed that such reactions occur through a one electron transfer followed by the migration of a hydrogen atom⁹. Chemical evidence supporting these mechanisms is provided by the demonstration of direct hydrogen transfer from dihydronicotinamide to the C(5) position of N(5)-deazaflavin, both in a model system¹⁰ and enzymatically¹¹.

This study was undertaken in order to visualise the associations between nicotinamide and flavin in their various oxidation states. In doing so, we have elucidated the structures of two oxidation states of a propyl linked flavin-nicotinamide biscoenzyme, $\text{Fl}_{\text{ox}}^- - \text{C}_3 - \text{Nic}^+$ and $\text{H}_2\text{Fl}_{\text{red}} - \text{C}_3 - \text{Nic}^+$. $\text{Fl}_{\text{ox}}^- - \text{C}_3 - \text{Nic}^+$: 10-[3-(3-carbamoyl-1-pyridinium)-propyl]-7,8-dimethylisalloxazine. $\text{Fl}_{\text{ox}}^- - \text{C}_3 - \text{Nic}^+$: The anion of $\text{Fl}_{\text{ox}}^- - \text{C}_3 - \text{Nic}^+$ generated by ionisation of the flavin N(3) position. $\text{H}_2\text{Fl}_{\text{red}} - \text{C}_3 - \text{Nic}^+$: 10-[3-(3-carbamoyl-1-pyridinium)-propyl]-1,5-dihydro-7,8-dimethylisalloxazine. $\text{HFl}_{\text{red}} - \text{C}_3 - \text{Nic}^+$: The anion of $\text{H}_2\text{Fl}_{\text{red}} - \text{C}_3 - \text{Nic}^+$ generated by the ionisation of the flavin N(1) position. These compounds, which were originally synthesised for model studies of the 1,4-dihydronicotinamide reduction of flavins², exhibit intermolecular associations that are of potential biological significance.

Experimental methods

$\text{Fl}_{\text{ox}}^- - \text{C}_3 - \text{Nic}^+ \cdot 7\text{H}_2\text{O}$ synthesis: $(\text{Fl}_{\text{ox}}^- - \text{C}_3 - \text{Nic}^+)\text{Br}^-$ was synthesised as previously described^{2,5}. Needle shaped yellow crystals were grown by the vapour equilibration of a 10 mM aqueous NH_3 solution with a 5 mM $(\text{Fl}_{\text{ox}}^- - \text{C}_3 - \text{Nic}^+)\text{Br}^-$ solution. Thin layer chromatography of these crystals followed by staining with AgNO_3 failed to reveal the presence of bromide ion. Hence the

crystals consist of the zwitterionic species $\text{Fl}_{\text{ox}}^- - \text{C}_3 - \text{Nic}^+$. A crystal measuring $0.16 \times 0.13 \times 0.62$ mm was sealed inside a thin walled glass capillary tube to prevent the observed disintegration of the crystals on exposure to air. Oscillation and Weissenberg photographs revealed the space group to be $\text{P}2_1/\text{c}$. The unit cell parameters are $a = 7.740(3)$, $b = 23.800(12)$, $c = 13.958(5)$ Å and $\beta = 101.93(3)^\circ$. The crystal density of 1.392 g cm^{-3} , as determined by flotation in a CCl_4 -cyclohexane mixture, indicates that the contents of the asymmetric unit are $\text{Fl}_{\text{ox}}^- - \text{C}_3 - \text{Nic}^+ \cdot 7\text{H}_2\text{O}$.

$(\text{H}_2\text{Fl}_{\text{red}} - \text{C}_3 - \text{Nic}^+)\text{NO}_3^- \cdot 4\text{H}_2\text{O}$ synthesis: The flavin moiety in an aqueous solution of $(\text{Fl}_{\text{ox}}^- - \text{C}_3 - \text{Nic}^+)\text{Br}^-$ at pH 8.0 was selectively reduced by dithiothreitol in anaerobic conditions. This caused the solution to change colour from the yellow characteristic of oxidised flavins to dark blue-black. After a day the zwitterionic species $\text{HFl}_{\text{red}}^- - \text{C}_3 - \text{Nic}^+$ had precipitated as black spherical clumps of crystallites that were unsuitable for X-ray study. These were dissolved at about 50°C in a minimal amount of 50 mM HNO_3 to form a dark brown solution. After several days, red plate-like crystals appeared. These crystals are stable in air for several minutes but longer exposures result in their disintegration and the return of the yellow colour of oxidised flavins.

A crystal measuring $0.75 \times 0.08 \times 0.12$ mm was sealed inside a thin walled glass capillary tube together with a small amount of 0.1 M $\text{Na}_2\text{S}_2\text{O}_4$ to act as an oxygen scavenger. Oscillation, Weissenberg and precession photographs showed the crystal to have triclinic lattice symmetry. The statistical distribution of the subsequently measured diffraction data indicated that the space group of the crystal was $\text{P}\bar{1}$. The unit cell parameters are $a = 8.068(3)$, $b = 11.369(3)$, $c = 14.190(7)$ Å, $\alpha = 77.89(3)^\circ$, $\beta = 88.99(4)^\circ$ and $\gamma = 89.12(3)^\circ$. The crystal density of 1.405 g cm^{-3} , as determined by flotation in a cyclohexane- CCl_4 mixture, indicated the stoichiometry of the asymmetric unit to be $(\text{H}_2\text{Fl}_{\text{red}} - \text{C}_3 - \text{Nic}^+)\text{NO}_3^- \cdot 4\text{H}_2\text{O}$.

A detailed description of the techniques used in intensity measurement, data treatment and structure determination for both of these compounds will appear elsewhere¹². For both crystals, reflection intensities were measured by a Picker FACS-I diffractometer using graphite monochromatised $\text{CuK}\alpha$ radiation. A total of 3,806 and 4,076 reflections, respectively, for $\text{Fl}_{\text{ox}}^- - \text{C}_3 - \text{Nic}^+$ and $(\text{H}_2\text{Fl}_{\text{red}} - \text{C}_3 - \text{Nic}^+)\text{NO}_3^-$ were measured to the limit $2\theta = 125^\circ$. Both structures were solved by the straightforward application of the direct methods program MULTAN¹³. In both cases all 30 non-hydrogen atoms of the $\text{Fl}_{\text{ox}}^- - \text{C}_3 - \text{Nic}^+$ skeleton appeared as the highest peaks in the E-map. Subsequent Fourier maps revealed the positions of the non-hydrogen atoms of seven water molecules in the case of $\text{Fl}_{\text{ox}}^- - \text{C}_3 - \text{Nic}^+$ and those of the nitrate ion and four water molecules for $(\text{H}_2\text{Fl}_{\text{red}} - \text{C}_3 - \text{Nic}^+)\text{NO}_3^-$.

The structures were refined by least-squares methods. Hydrogen atoms were located in difference Fourier maps and were subsequently also refined. Seven solvent hydrogen atoms could not be located in the $\text{Fl}_{\text{ox}}^- - \text{C}_3 - \text{Nic}^+$ structure and, similarly, four methyl hydrogens and two water hydrogens were not found in that of $(\text{H}_2\text{Fl}_{\text{red}} - \text{C}_3 - \text{Nic}^+)\text{NO}_3^-$. The refinements converged at the final agreement factors of $R = 0.064$ based on 3,318 observed reflections for $\text{Fl}_{\text{ox}}^- - \text{C}_3 - \text{Nic}^+$ and $R = 0.069$ based on 2,963 observed reflections for $(\text{H}_2\text{Fl}_{\text{red}} - \text{C}_3 - \text{Nic}^+)\text{NO}_3^-$.

Molecular structures

$\text{Fl}_{\text{ox}}^- - \text{C}_3 - \text{Nic}^+$: The final atomic parameters of the structures together with their covalent distances and angles will be presented elsewhere¹². Figure 1 illustrates the conformation of the $\text{Fl}_{\text{ox}}^- - \text{C}_3 - \text{Nic}^+$ zwitterion and presents the atomic numbering scheme. The covalent bonding parameters are mostly in excellent agreement with published values of corresponding distances and angles in similar molecules¹⁴⁻¹⁹. The only significant exceptions to this are the predictable distortions of the flavin pyrimidinoid ring in the region of the ionised N(3) atom^{14,20}. The flavin residue is nearly planar as has been found for other oxidised flavins². The root mean square deviation of its 18 atoms from coplanarity is 0.026 Å. That of

Fig. 1 A perspective drawing of the $\text{Fl}_{\text{ox}}^- - \text{C}_3 - \text{Nic}^+$ zwitterion. Atoms are shown as thermal ellipsoids.

Fig. 2 A stereo diagram illustrating the packing of the $\text{Fl}_{\text{ox}}^- - \text{C}_3 - \text{Nic}^+$ unit cell. The view is roughly along the a axis with the b and c axes extending vertically and horizontally, respectively. Water oxygen atoms are illustrated as thermal ellipsoids. Hydrogen bonds and $\text{C}-\text{H} \cdots \text{O}$ hydrogen bond-like interactions are shown as dashed and dotted lines, respectively. Hydrogen atoms have been omitted for clarity.

the 6 atoms of the nicotinamide ring is 0.005 Å, so this ring is planar to within experimental error. The amide group is oriented such that the $\text{C}(7\text{N})-\text{N}(7\text{N})$ bond is *trans* to the $\text{N}(1\text{N})-\text{C}(3')$ bond with the planes of the amide group and the nicotinamide ring forming a dihedral angle of 1.1° . This nearly coplanar conformation is found in a majority of the known nicotinamide structures^{16-19,22}.

The propyl group is in the all *trans*, fully extended conformation. The least-squares planes through the nicotinamide and flavin rings form a dihedral angle of 59.5° .

Figure 2 is a stereo diagram showing the packing of the structure in the unit cell. The crystal structure largely consists of broad bands, endlessly extending parallel to the (010) plane, that contain the $\text{Fl}_{\text{ox}}^- - \text{C}_3 - \text{Nic}^+$ zwitterions. Within these bands the flavin residues associate by forming endless stacks of overlapping parallel ring molecules. Here neighbouring molecules are related by centres of symmetry. The distances between the least-squares planes of the parallel flavin residues are 3.460 and 3.385 Å, respectively, for the two different stacking interactions. There is no interatomic contact in either interaction that is less than its corresponding van der Waals distance. Hence these associations are normal stacking interactions.

The nicotinamide residues extend alternately to opposite sides of the flavin stacks. The nicotinamide rings within a given band of heterocycles are parallel due to symmetry considerations. As can be seen in Fig. 2, however, neighbouring nicotinamide residues do not overlap.

The only hydrogen atoms of the $\text{Fl}_{\text{ox}}^- - \text{C}_3 - \text{Nic}^+$ zwitterion that are capable of forming normal hydrogen bonds are those of the amide group. Of these, only one participates in a hydrogen bond between the nicotinamide and flavin moieties of the structure. This is the intermolecular $\text{N}(7\text{N})-\text{H}(20) \cdots \text{O}(4)$ hydrogen bond illustrated in Figs 2 and 3. This interaction is flanked by an apparently strong intermolecular $\text{C}(4\text{N})-\text{H}(16) \cdots \text{O}(4)$ hydrogen bond-like interaction. Both of these interactions are unusual in that the nicotinamide and flavin planes are more nearly perpendicular than parallel to each other. Flavin atom $\text{N}(5)$, a potential hydrogen bond acceptor, is 2.86 Å from amide hydrogen $\text{H}(20)$. This is, however, too large a distance to be considered a hydrogen bond.

The bands containing the $\text{Fl}_{\text{ox}}^- - \text{C}_3 - \text{Nic}^+$ zwitterions are interspersed by parallel bands containing the solvent molecules. These are arranged in a complex hydrogen bonded network which also involves the hydrophilic groups of the $\text{Fl}_{\text{ox}}^- - \text{C}_3 - \text{Nic}^+$ zwitterion.

$\text{H}_2\text{Fl}_{\text{red}} - \text{C}_3 - \text{Nic}^+$: Figure 4 illustrates the conformation of the $\text{H}_2\text{Fl}_{\text{red}} - \text{C}_3 - \text{Nic}^+$ ion and the atomic numbering scheme. The covalent bonding parameters are in reasonable agreement with the corresponding values reported for other 1,5-dihydroisalloxazine derivatives.

The eight atoms of the pyrimidinoid group and the six atoms of the benzenoid ring of the flavin moiety deviate from their respective least-squares planes by root mean square distances of 0.006 and 0.012 Å. Hence these rings are both highly planar. The reduced flavin nucleus assumes the expected 'butterfly' confor-

mation²³ with a 12.7° dihedral angle between the foregoing planes. The corresponding angles in the four previously reported 1,5-dihydroflavin structures range from 28.8 to 35.5° (refs 21, 24)—all more than twice that found in the present structure. The pyrazoid ring is in the usual boat conformation.

The nicotinamide ring is also highly planar. Its six atoms deviate from their least-squares plane by a root mean square distance of 0.008 Å. The amide group in this ion is roughly *trans* to the $\text{N}(1\text{N})-\text{C}(3')$ bond but is twisted about the $\text{C}(3\text{N})-\text{C}(7\text{N})$ bond such that the $\text{C}(2\text{N})-\text{C}(3\text{N})-\text{C}(7\text{N})-\text{O}(7\text{N})$ torsion angle is 29.4° .

The propyl group is folded such that the conformation about its $\text{C}(2')-\text{C}(3')$ bond is *gauche* and that about its $\text{C}(1')-\text{C}(2')$ bond is *trans*. The dihedral angle between the least-squares planes through the nicotinamide ring and the entire flavin residue is 73.4° .

Figure 5 is a stereo diagram illustrating the packing of the structure in the unit cell. It can be seen that the flavins associate,

Fig. 3 A perspective drawing illustrating the hydrogen bonding interactions between the flavin and nicotinamide residues of neighbouring molecules in the structure of $\text{Fl}_{\text{ox}}^- - \text{C}_3 - \text{Nic}^+$. Atoms are shown as thermal ellipsoids. Hydrogen bonds and $\text{C}-\text{H} \cdots \text{O}$ hydrogen bond-like interactions are represented by thin and dashed lines, respectively, and are accompanied by their corresponding lengths (Å).

Fig. 4 A perspective drawing of the $\text{H}_2\text{Fl}_{\text{red}}\text{-C}_3\text{-Nic}^+$ ion. Atoms are shown as thermal ellipsoids

through stacking and hydrogen bonding interactions, into bands of ring molecules endlessly extending parallel to the (001) plane. Neighbouring heterocycles within the columns of stacked flavins are related by centres of symmetry. Their butterfly conformation thereby causes them to alternately fold towards and away from each other. There are no interatomic contacts closer than van der Waals distances within these stacks.

Neighbouring flavins base pair across centres of symmetry in a manner by which flavins have often been observed to associate²⁵. The $\text{N}(3)\text{-H}(2)\cdots\text{O}(2)$ hydrogen bond length of 2.796 Å is within the normal range for such interactions¹⁴.

The nicotinamide residues alternately extend to opposite sides of the flavin stacks and are oriented such that they are nearly parallel to the flavin stacking axis. The nicotinamide groups are too far removed from one another to associate in any manner.

The nicotinamide amide oxygen $\text{O}(7\text{N})$ accepts a tenuous hydrogen bond from the flavin $\text{N}(5)\text{-H}(3)$ group of a neighbouring $\text{H}_2\text{Fl}_{\text{red}}\text{-C}_3\text{-Nic}^+$ ion. This association, illustrated in Figs 5 and 6, seems to be quite strained. The $\text{N}(5)\cdots\text{O}(7\text{N})$ and the

$\text{H}(3)\cdots\text{O}(7\text{N})$ distances of 3.184 and 2.53 Å, respectively, are very long for $\text{N-H}\cdots\text{O}$ hydrogen bonds. The $\text{N}(5)\text{-H}(3)\cdots\text{O}(7)$ angle of 152° deviates significantly from the expected near linearity for such interactions. Furthermore, although an amide group is normally expected to be essentially coplanar with an N-H group to which it is hydrogen bonded, flavin atoms $\text{N}(5)$ and $\text{H}(3)$ deviate 2.399 and 1.98 Å, respectively, from the plane of the amide group with which they are associated. In fact, without the large $\text{C}(2\text{N})\text{-C}(3\text{N})\text{-C}(7\text{N})\text{-O}(7\text{N})$ torsional angle, the foregoing hydrogen bond could not be formed.

The regions in the crystal structure between the associating $\text{H}_2\text{Fl}_{\text{red}}\text{-C}_3\text{-Nic}^+$ ions are occupied by the nitrate ions and the solvent molecules. These associate through hydrogen bonded networks that involve the hydrophilic groups of the heterocycles. All potential hydrogen bonds in the structure seem to have been formed.

Discussion

Studies of the nitroalkane reduction of the FAD requiring enzyme D-amino acid oxidase have proven that, at least in certain classes of enzymatic reactions, the flavin $\text{N}(5)$ atom is the position through which electrons are transferred²⁶. This is further corroborated by the reduction of $\text{N}(5)$ -deazaflavin by direct hydrogen transfer to its $\text{C}(5)$ position^{10,11}. Thus it is of interest that the flavin $\text{N}(5)\text{-H}(3)$ group is hydrogen bonded to nicotinamide atom $\text{O}(7\text{N})$ in $\text{H}_2\text{Fl}_{\text{red}}\text{-C}_3\text{-Nic}^+$.

The $\text{C}(4)$ atom of nicotinamide is known to be the position through which electrons are transferred in the biological oxidation-reduction reactions of pyridine nucleotides. It is therefore of note that in $\text{Fl}_{\text{ox}}\text{-C}_3\text{-Nic}^+$ the $\text{C}(4\text{N})\text{-H}(16)$ group forms a hydrogen bond-like association with flavin atom $\text{O}(4)$.

The nicotinamide amide group has been shown not to be an essential component of NAD^+ in the reactions mediated by certain dehydrogenases²⁷. Rather, it seems that a major requirement for the activity of these enzymes is that the substituent to the pyridinium 3-position be a carbon atom that is double bonded to an electronegative atom, such as O, N or S²⁷. Nevertheless, it seems likely that the amide group of nicotinamide serves a specific function in some vital biological process for without such a function it is expected that evolutionary processes would have chemically altered the amide group in some manner in at least some organisms. The similarities of the nicotinamide-flavin associations in both structures presented here suggest that the function of the nicotinamide amide group during enzyme mediated reduction of flavin by 1,4-dihydronicotinamide may be to bind the reactive portions of flavin and nicotinamide together to facilitate electron transfer.

The observed 12.7° bending angle of the 1,5-dihydroflavin

Fig. 5 A stereo drawing illustrating the crystal structure of $(\text{H}_2\text{Fl}_{\text{red}}\text{-C}_3\text{-Nic}^+)\text{NO}_3^-\cdot 4\text{H}_2\text{O}$ in relation to the unit cell boundaries. The view is roughly along the c axis with the a and b axes extending horizontally and vertically, respectively. Water oxygen atoms and the atoms of the nitrate ion are shown as thermal ellipsoids. Hydrogen bonds between heterocycles are shown as dashed lines. Hydrogen atoms have been omitted for clarity.

moiety of $\text{H}_2\text{Fl}_{\text{red}}\text{-C}_3\text{-Nic}^+$ is considerably less than the 32° average of this angle in the previously reported 1,5-dihydroflavin structures^{21,24}. All of these latter compounds have more and bulkier substituents than does the flavin residue in $\text{H}_2\text{Fl}_{\text{red}}\text{-C}_3\text{-Nic}^+$ and hence it might seem that their large bending angles are due to steric interference among these substituents. Molecular models of these compounds, however, reveal that such overcrowding is relieved at bending angles of the order of 10° . Furthermore, a similarly substituted fully oxidised flavin is observed to be nearly planar²⁸

Fig. 6 A perspective drawing illustrating the hydrogen bonding association of the flavin and nicotinamide residues of neighbouring molecules in the structure of $\text{H}_2\text{Fl}_{\text{red}}\text{-C}_3\text{-Nic}^+$. Atoms are shown as thermal ellipsoids. The hydrogen bond is represented by a thin line accompanied by its length (Å).

Self-consistent field molecular orbital calculations incorporating the PRDDO (partial retention of diatomic differential overlap) approximation indicate that the barrier for ring inversion in 1,5-dihydroflumiflavin has a surprisingly low value of nearly 4 kcal mol^{-1} (Lindner, D. L., Branchaud, B., Dixon, D. A., and Lipscomb, W. N., to be submitted). Nuclear magnetic resonance (NMR) measurements on several reduced flavin derivatives yield a larger but still relatively low value of 10 kcal mol^{-1} for this barrier²⁹. Therefore the observation that there is considerable flavin/flavin stacking in the crystal structure of $\text{H}_2\text{Fl}_{\text{red}}\text{-C}_3\text{-Nic}^+$ but very little ring overlap in the structures of other reduced flavins^{21,24} suggests that the small flavin bending angle in $\text{H}_2\text{Fl}_{\text{red}}\text{-C}_3\text{-Nic}^+$ is due to the influence of stacking interactions.

X-ray studies of flavodoxin from *Clostridium MP* have shown, as expected, that the flavin moiety of the bound FMN cofactor is planar in both the oxidised^{30,31} and the semiquinone^{31,32} forms of the enzyme. The flavin residue is also nearly planar in reduced *Clostridium* flavodoxin; its bending angle is estimated to be 8.6° (ref 31). This is corroborated by the essential identity of the NMR spectra of oxidised and reduced *Clostridium* flavodoxins³³.

It has been suggested that the constraint of a protein bound reduced flavin to the planar configuration enhances its reducing power by modifying its redox potential^{29,31,34}. The nearly planar conformation of the flavin moiety in $\text{H}_2\text{Fl}_{\text{red}}\text{-C}_3\text{-Nic}^+$ cor-

roborates this hypothesis by demonstrating the flexibility of the flavin bending angle.

The red colour of $(\text{H}_2\text{Fl}_{\text{red}}\text{-C}_3\text{-Nic}^+)\text{NO}_3^-$ crystals, in contrast to the yellow colour of other crystalline reduced flavins^{21,24} might reasonably be attributed to either a charge-transfer complex or a spectral shift in the reduced flavin caused by its flattening²³. Charge-transfer interactions have been observed between stacked oxidised flavin molecules in the crystalline complex lumiflavin-2,6-diamino-9-ethyladenine³⁵ but have not been previously observed between reduced flavin molecules. The most likely site for such an interaction in the structure of $\text{H}_2\text{Fl}_{\text{red}}\text{-C}_3\text{-Nic}^+$ is within the stacks of reduced flavins. However, the fact that all interatomic contacts between reduced flavin residues are greater than van der Waals distances indicates that any charge transfer forces present would be weak at best. Likewise, the relatively small changes in the visible absorption spectrum of the nearly planar flavin molecule of reduced flavodoxin from *Clostridium MP*, in comparison with that of free reduced FMN³⁶, do not account for the red colour of crystals of $(\text{H}_2\text{Fl}_{\text{red}}\text{-C}_3\text{-Nic}^+)\text{NO}_3^-$. Hence the origin of this colour remains obscure.

Our study provides no evidence supporting the face-to-face charge-transfer complex model of flavin/nicotinamide interactions postulated on the basis of solution studies²⁻⁵. The absence of such associations in the structure of $\text{H}_2\text{Fl}_{\text{red}}\text{-C}_3\text{-Nic}^+$ corroborates the observation that these interactions are relatively weak⁵. This is in agreement with the assertion that the characteristics of charge-transfer complexes are highly dependent on the relative orientations of the donor and the acceptor and on the contribution of other weak binding forces to the total potential energy of the complex³⁷. Thus it seems likely that the formation of any face-to-face flavin/nicotinamide complex in aqueous solutions would require stabilisation by hydrophobic forces similar to those promoting the stacking of nucleic acid bases in aqueous solutions³⁸.

We thank W. N. Lipscomb for providing the results of the molecular orbital calculations on flavins before publication. This work was supported, in part, by grants from the US NIH (GM 11040) and the MRL program of the NSF (DMR76-00678).

Possible regulatory function of acetylcholine receptor in maintenance of retinotectal synapses

John A. Freeman

Vanderbilt University Medical School, Nashville, Tennessee 37232 and National Institute for Medical Research, London NW7, UK

α -Neurotoxins bind to cholinergic receptor, block transmission, and induce sprouting of retinal terminals in the toad tectum. New connections retain an orderliness that suggests a selective affinity between presynaptic terminals. The results suggest that postsynaptic cells exert a control, associated with receptors, on the growth of presynaptic terminals and on the maintenance of their synaptic connections.

THE effects of the presynaptic element of a synapse on the physiological and metabolic properties of its postsynaptic component have been extensively studied in several systems. But little is known about the influences which the postsynaptic element of a synapse might exert on the selection, maintenance, or metabolic control of its presynaptic component. Such information might provide important insights into the molecular mechanisms underlying growth, repair, and the response to injury in the central nervous system (CNS). The amphibian retinotectal system provides a useful model. The retina projects in an orderly visuotopic map on to the tectum, where the terminals from different classes of ganglion cells form synapses in separate layers^{1,2}. Moreover, the optic nerve will regenerate³, and in doing so re-establish a nearly identical pattern of connections^{4,5}.

Functional connections require a matching between neurotransmitter and postsynaptic receptor protein. Evidence has recently been obtained that acetylcholine (ACh) is an excitatory neurotransmitter in the amphibian optic tectum, and might be utilised by at least two different classes (I and IV) (ref. 1) of retinal ganglion cells. For example, (1) the retinotectal synaptic layers contain high levels of ACh, choline acetyltransferase, and ACh-esterase⁶; (2) tectal cells are excited by iontophoretically-applied ACh and synaptic responses are blocked by nicotinic antagonists⁷; (3) the reversal potentials for both iontophoretically applied ACh and the native transmitter are the same, indicating similar permeability mechanisms (manuscript in preparation); and (4) optic nerve terminal-associated synaptosomes possess a high affinity uptake system for choline, and also bind snake venom α -neurotoxins (J. A. F. and R. Oswald, in preparation). In addition, α -bungarotoxin (α -BTX) and related polypeptide α -neurotoxins, which selectively bind to nicotinic acetylcholine receptor protein (ACh-R) at neuromuscular junction^{8,9}, also bind to synapses in the tectal neuropil^{10,11}, and produce a long-lasting abolition of retinotectal transmission^{7,10}. Light autoradiographs using tritiated α -BTX reveal a distinct trilaminar distribution of receptor sites^{10,11} corresponding to the distribution of retinal terminals.

These experiments were designed to determine whether receptor-mediated changes in transmission affecting the postsynaptic cell influence the growth of presynaptic terminals. I report here that dynamic changes in the patterns of retinotectal connections occur after application of α -neurotoxins to tectal neurones in the South American toad *Bufo marinus*. The results, obtained by the use of a new mapping technique, suggest that the maintenance of synapses requires functional interaction between transmitter and receptor.

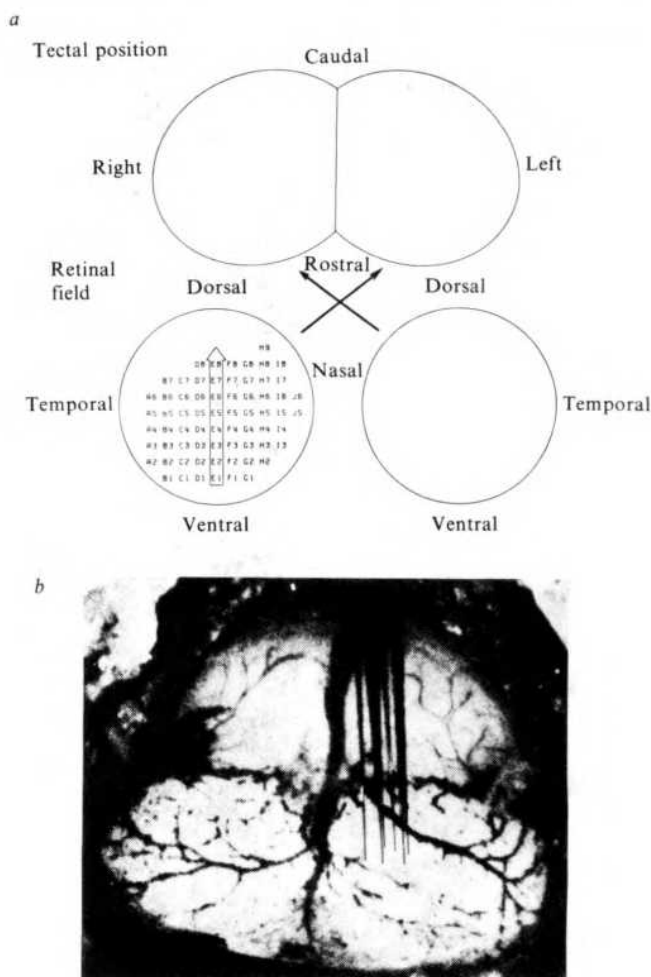

Fig. 1 Retinotectal mapping technique. Animals were immobilised either by spinal epidural anaesthesia (0.3 ml of 0.5% lidocaine in 2% sucrose) or by cooling the trunk and limbs in ice, and the tecta exposed, using a local anaesthetic. Spontaneous eye movements were eliminated by the use of a small ring held against the sclera. The optical axis of the eye, determined ophthalmoscopically, was centred on a Tektronix 611 CRT screen on which were presented electronically-generated patterns whose shape, position and brightness were controlled by a PDP-12 computer. The size and position of the equivalent retina image was computed from the translation-refraction matrix of the reduced eye. A standardised grid of retinal loci (a) was activated covering 140° of solid visual angle, and for each retinal locus the corresponding area of representation in the contralateral tectum was determined by measuring the laminar field potentials with an array of six microelectrodes (b), consisting of glass micropipettes filled with toad Ringer's, whose tips (bevelled for easier penetration¹²) were positioned 100 μ m apart in a 2 \times 3 grid. Computer-averaged field potentials were combined with previously determined extracellular resistivities to compute the three-dimensional current source density (CSD), thereby providing a clear separation of pre- and postsynaptic responses, facilitating a direct comparison of maps to be made between different animals, or in the same animal mapped at different times.

Fig. 2 Laminar field potentials (a) and corresponding CSDs (b) generated in optic tectum at indicated depths beneath the surface by the turning off of a 2° spot of light. 'Off' fibres produce a prominent sink at a depth of 300 μm , the postsynaptic component of which (arrow) is associated with a set of superficial (100–200 μm) and deep (450 μm) sources drawn from radially oriented tectal dendrites. The more superficial (100–150 μm) longer latency class II fibres are also clearly localised in (b). Calibration pulses at beginning of field potential records: 500 μV , negativity upwards. Same amplitude on CSD records corresponds to 10 mA cm^{-2} , sink upwards.

Mapping retinotectal projections

To detect subtle changes that might occur in the positions of retinal terminals, a new mapping technique was devised, in which the retina was stimulated visually at regularly spaced loci (Fig. 1). The actual tectal location of the retinal terminals thus activated was determined by searching the tectum with an array of six microelectrodes and computing the extracellular current source density (CSD) (refs 13–15). The CSD, obtained by computing the divergence of the field potential weighted by the extracellular conductivity, represents the net transmembrane flux in a specified volume of tissue¹⁴. For measurements obtained at an interelectrode spacing of N , the CSD localises activity originating in an interval of $N/2$ (or 50 μm in the present study)¹⁵.

It has recently been shown¹⁶ that an extracellular microelectrode selectively records the activity of retinal terminals (which branch extensively, thereby providing a greatly increased extracellular current) rather than of fibres of passage, although it records postsynaptic activity as well. An additional advantage of the CSD technique is that it readily distinguishes between pre- and postsynaptic activity^{2,13,15}.

The following results deal primarily with class IV retinal terminals¹ ('off' fibres), which respond selectively to a sudden decrease of illumination of their receptive fields. These terminals, which synapse on dendrites of tectal neurones whose somas lie in the central grey strata¹⁷, occupy a compact lamina 300 μm below the tectal surface. Their location is shown in the CSD records of Fig. 2b.

Separation of visually evoked potentials into pre- and postsynaptic components by CSD analysis is shown more clearly in Fig. 3, which also demonstrates the nicotinic cholinergic nature of class IV retinotectal synapses. In Fig. 3a, a 10^{-9} M solution of *d*-tubocurarine was applied to the tectal surface. At time 'zero' (control), the CSD waveform computed from responses to visual stimuli consists of two components: an early presynaptic sink, followed by a postsynaptic sink produced by dendritic depolarisation. This second component is gradually abolished over the next 15 min, and returns to near control values after 60 min. Figure 3b shows the CSD responses obtained at the same location in response to electrical stimulation of the optic nerve, after application to the tectal surface of a $1 \cdot 10^{-9}$ M solution of α -TBX. Initially (time zero) the early presynaptic sink is followed by a prominent postsynaptic sink, which, however, is irreversibly abolished after 180 min. The toxin produced no detectable change in the presynaptic response.

Experiments were performed in eight animals to determine the normal sequence of regeneration of retinal fibres after a lesion of the optic nerve. The projections of the intact optic nerve were first determined by CSD mapping. One optic nerve was then gently crushed at a distance of approximately 2.5 mm from the optic chiasm, and each animal, maintained at 20–24 °C, was remapped at various times thereafter. The earliest evidence of re-entry of regenerating fibres into the tectum occurred at 10–14 d. The earliest patterns of presynaptic terminals were highly variable with little if any organisation. Over the ensuing 2–3 weeks considerable organisation occurred, and by 6–8 weeks after the lesion the pattern of retinal projections differed very little from the original pattern.

Effect of toxin application on retinotectal projections

α -BTX was applied to a discrete region of tectum by placing a small square of Millipore filter soaked in toxin (5×10^{-9} M)

Fig. 3 Abolition of postsynaptic response to 'off' fibres by nicotinic antagonists. The lyophilised venom of *Bungarus multicinctus* was purified by chromatography on SP-Sephadex (C-25). The peak corresponding to α -BTX was collected and shown to be homogeneous on polyacrylamide gel electrophoresis using the technique of Reisfeld *et al.*¹⁸. An *in vivo* assay of toxicity was performed on toad sartorius muscle, using intracellular recording. A dose of $1 \cdot 10^{-9}$ M caused complete loss of synaptic transmission within 30 min, with no discernable loss of presynaptic activity recorded simultaneously with a second extracellular microelectrode. In (a), a 10^{-9} M solution of *d*-tubocurarine caused reversible block of transmission in which the postsynaptic component (arrow) is gradually abolished in 15 min, but returns to near control value after 60 min. CSD records computed at 300 μm depth, following turning off of a 3° light spot at beginning of each record. In (b), $1 \cdot 10^{-9}$ M α -BTX caused irreversible block of postsynaptic response to electric stimulation of optic nerve (arrow). Stimulus artefact was electronically suppressed. Average of 50 responses in (a), and 5 responses in (b). Calibration: 5 mA cm^{-2} in (b), sink upwards.

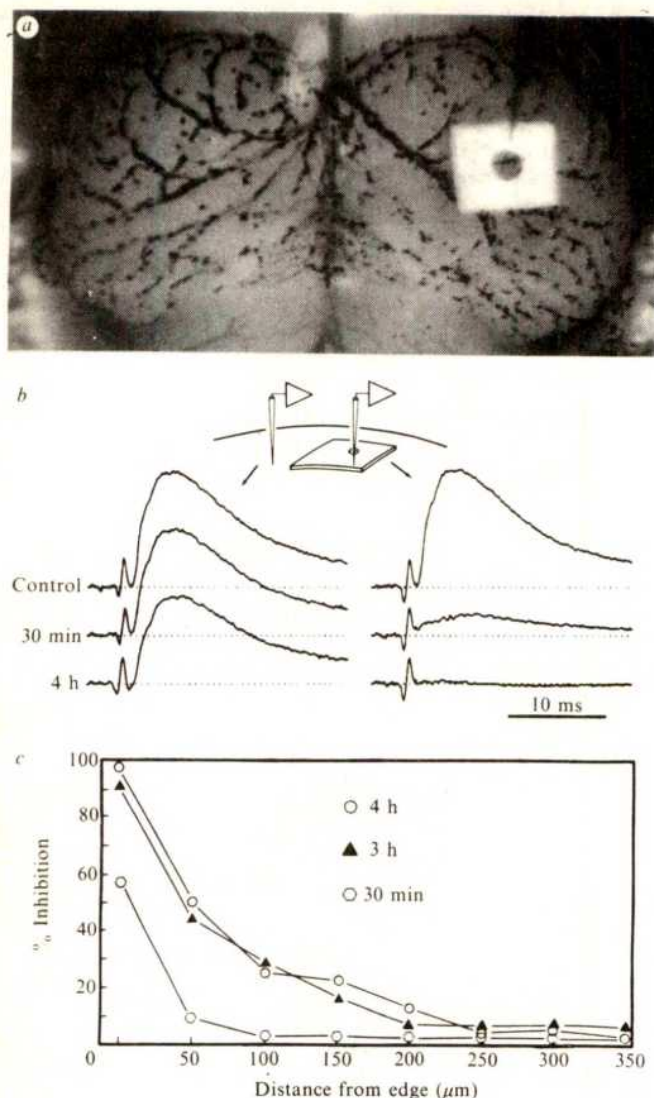

Fig. 4 Application of α -BTX to discrete region of tectum. A small square (approximately $700 \times 700 \mu\text{m}$) of α -BTX-soaked (5×10^{-9} M) Millipore filter was placed on the tectal surface (a). Two microelectrodes, one (dark shadow) inserted through a central hole, and the other inserted at various distances from the edge of the filter, were used to compute current source densities from responses to class IV fibres activated by shocking optic nerve. Postsynaptic responses were blocked immediately underneath filter (b, right side) but were relatively unaffected 250 μm from edge of filter (b, left side) over a 4-h period. (c) Inhibition (relative to control value before toxin application) of postsynaptic responses at indicated times and positions with respect to one edge of filter. Lack of synaptic blockade beginning approximately 250 μm outside of toxin-treated zone at 4 h (open circles) shows that little toxin diffused away from region of application.

on the tectal surface. To determine the extent of spread of toxin applied in this manner, a small square of filter was prepared with a hole cut in its centre, through which a microelectrode was lowered as shown in Fig. 4a. In Fig. 4b, the postsynaptic responses to optic nerve stimulation were progressively abolished underneath the filter over a period of 4 h, but were not significantly reduced outside of a region beginning approximately 250 μm from a side, presumably due to low diffusional mobility of toxin coupled with a high affinity of toxin-binding sites located under the region of application. The spatial and temporal spread of postsynaptic blockage produced by locally applied α -BTX is shown in Fig. 4c.

In seven animals, a small square of Millipore filter soaked in 5×10^{-9} M α -BTX was applied to the tectal surface two weeks after lesioning the contralateral optic nerve, when the re-

generating retinal fibres were beginning to re-enter the tectum. The filter was left in place for 4–5 h, its position photographed for later comparison, and then removed, and the animals were subsequently remapped at various times thereafter. Figure 5 shows the results of one such experiment. The map illustrated in Fig. 5b, obtained 20 d post-lesion (6 d after toxin application), shows the presence of presynaptic terminals within the toxin-treated zone, but otherwise has little organisation. By contrast, in the map obtained 14 d later (Fig. 5c), the toxin-treated zone lacked any evidence of presynaptic terminals, which instead seem to be clustered and compressed about its margins. Similar results were obtained from five other animals. On the other hand, three control animals (in which the filter was soaked in toad Ringer's rather than in α -BTX) mapped at this time, as well as another group of four animals mapped 20–30 weeks after toxin application, had an essentially normal pattern of projection with no evidence of compression.

One explanation for these effects might be that toxin killed the cells in the zone where it was applied, but that they subsequently regenerated. This seems unlikely, inasmuch as neurones remained normally responsive to other (for example, diencephalic¹⁹) inputs after toxin application, as shown by CSD analysis and single unit recording performed both during the early period (3–8 d) when toxin might be expected to produce a maximum effect, as well as at later times (2–6 weeks). A second possibility is that toxin prevented the formation of synapses. Similar experiments^{20,22} with chronic α -BTX application at the myoneuronal junction suggest that nerve-muscle synapses can in fact form when ACh-R is bound with toxin (although the possibility that they form only after bound toxin has been displaced from the receptor has not been conclusively demonstrated). A third possibility is that synapses, initially formed between regenerating terminals and α -BTX-treated tectal neurones, failed to be maintained, and that the presynaptic element continued its growth in search of a surface on which it could form an enduring synapse.

To test the effect of α -BTX on the maintenance of retino-tectal synapses, toxin was applied to the intact tectum in six animals, and the retinotectal projections were subsequently mapped at intervals of 7 d thereafter. The results from one animal are shown in Fig. 6, and are similar to those obtained from the others. One week after toxin application little if any presynaptic activity could be elicited from the toxin-treated zone (Fig. 6b) and the presynaptic terminals seemed to have shifted position and to have compressed into the borders surrounding it, displacing terminals previously located there (Fig. 6a). As shown by CSD analysis, some aberrant terminals evoked postsynaptic responses, signifying the formation of functional synapses, although the postsynaptic response amplitude was quite variable and was not easily quantitated. Maps made two weeks later (Fig. 6c) have essentially returned to normal, again suggesting that a dynamic, neuroplastic re-ordering of terminals has occurred.

These results show that the loci from which retinal terminals can be recorded change in a characteristic way after application of α -BTX. To account for these results, possible causes for the apparent sprouting, displacement, and subsequent reordering of retinal terminals should be considered.

Sprouting of retinal terminals

Several possibilities could account for the apparent shift in position of retinal terminals following the application of α -BTX shown in Figs 5 and 6, including (1), migration of postsynaptic cells²³ and their inputs; (2), unmasking of 'silent' terminals^{24,25} normally present and (3), active growth (that is, sprouting) of terminals. The first possibility is unlikely, since cells in toxin-treated regions which normally receive convergent inputs from both retinal and non-retinal (for example, diencephalic) afferents continued to respond to the latter, and were thus not likely to have migrated. The second possibility is also unlikely, since any 'silent' retinal terminals would have de-

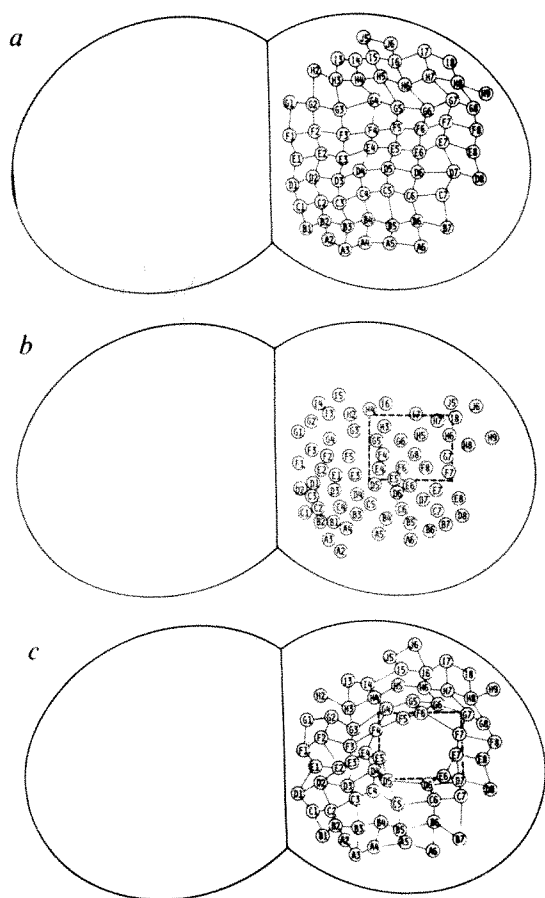

Fig. 5 Effect of localised application of α -BTX on pattern of regenerating retinal terminals. Control map shown in (a), representing positions (computed by CSD analysis) of class IV retinal terminals activated by stimulation of contralateral retinal loci shown in Fig. 1(a). Corresponding pattern of regenerating terminals shown in (b), 20 d after lesion of contralateral optic nerve, and 6 d after application of α -BTX to region indicated by dashed lines. Note the presence of terminals within the toxin-treated zone, and the general lack of organisation of the regenerating terminals. Considerable order has been restored in (c), made two weeks later. At this time, however, the toxin-treated zone is almost completely devoid of terminals, which appear clustered about its borders.

generated following optic nerve lesions. It is likely, therefore, that the results represent active growth of retinal terminals in response to toxin application, which as shown in the acute experiments of Figs 3b and 4b blocked synaptic transmission. Chronic block of neuromuscular transmission with tetanus²⁶ or with botulinum²⁷ toxin has been shown to result in sprouting of presynaptic terminals, which is suppressed by implantation of an extra nerve²⁸. Together, these results suggest that the postsynaptic element of a synapse might exert a trophic influence, dependent on the status of functional transmission, on the presynaptic element.

Similarly, the absence of detectable presynaptic activity in Figs 5c and 6b could also be accounted for by terminals growing away from the toxin-treated zones. On the other hand, some of the original terminals may have remained in the zone, but failed to produce sufficient extracellular current to be detected by the CSD technique if either the number or surface area was substantially decreased, or if chronically applied toxin interfered with the generation of action potentials (for example by binding to presynaptic ACh-R (ref. 29) or some other membrane component and altering membrane permeabilities or molecular structure). Chronic application of α -BTX for 10 d did not, however, produce any detectable decrement in action potentials in either optic nerve or sciatic nerve. Alternatively, terminals

may have degenerated, due to some primary effect of α -BTX, trace amounts of β -BTX (ref. 30) (not detectable by chromatography or gel electrophoresis), or a secondary loss of some required trophic factor. A recent³¹ electron microscopic examination of rat neuromuscular junction chronically treated with α -BTX showed no evidence of degeneration of nerve terminals, and I found no evidence of terminal degeneration in preliminary light microscopic examinations of toxin-treated regions, but detailed EM examination has not yet been done.

Displacement of retinal terminals

Maps made one week after toxin application (Fig. 6b) reveal an apparent displacement of terminals normally occupying the borders of the toxin-treated zone. Some terminals in these border regions seemed to have been displaced by as much as 250 μ m whereas terminals normally located within the toxin-treated zone seemed to have been displaced by as much as 600–700 μ m. Since the accuracy with which the eye's optical

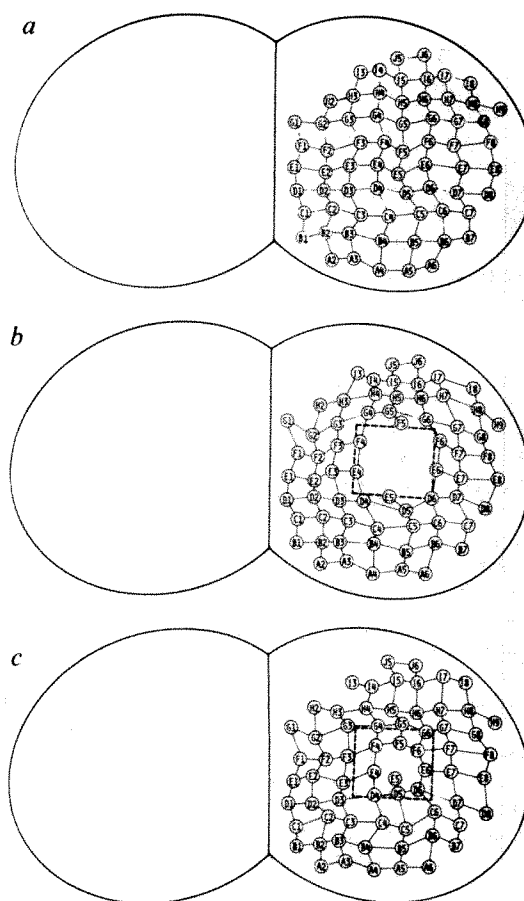

Fig. 6 Plastic changes in positions of class IV terminals following localised application of α -BTX to normally innervated tectum. Control map shown in (a). In (b), obtained one week later after applying square of Millipore filter soaked in α -BTX to region indicated by dashed lines, terminals previously located there (for example, E4-E6, F4-F6, G5) have shifted position and compressed into regions near borders, displacing terminals previously located there. In (c), obtained two weeks later, terminals have essentially returned to their original positions. Quantitative measurements of the amount of compression and order in the projections of displaced terminals in (b) were made by computing the mean distance between each recorded terminal site and its eight nearest neighbours, as well as its eight 'appropriate' neighbours. The results showed that a displaced terminal had a higher probability of retaining the same relative relationships with its displaced neighbours as with its original neighbours than any other relationship. This suggests that some selective interaction exists between terminals of neighbouring retinal ganglion cells.

axis can be precisely realigned is limited, the absolute displacement is less certain than is the relative displacement. This may represent a change in dendritic morphology of tectal neurones, or a true shift in the alignment of pre- and postsynaptic elements. An effort to differentiate between these two possibilities was made by mapping the lateral extent of antidromic field potentials generated by dendrites^{15,32} in response to focal microstimulation of tectal neuronal cell bodies in the central grey strata, by a stimulating microelectrode. The mean diameter of tectal dendritic fields estimated in this way was $110 \pm 20 \mu\text{m}$. No significant variation of dendritic field size was found within or surrounding the toxin-treated zone. This suggests that the displacement in the position of terminals in the border zones represents a true change in alignment of pre- and postsynaptic elements. As seen in Figs 5c and 6b, displaced terminals tended to retain their original orientation with respect to each other rather than to distribute randomly. The retention of a high degree of order between both invading as well as displaced terminals suggests the existence of a selective interaction between neighbouring terminals.

Reordering of retinal terminals

If the preceding interpretations are correct, both the original displacement and the subsequent reordering of retinal terminals seen in Fig. 6c represent sprouting. One would expect the sprouting terminals to ramify in the vicinity of the receptor-blocked cells, and to form contacts there. The apparent failure for this to occur implies that sites capable of receiving synapses did not exist on the receptor-blocked cells, and that the sprouting terminals did not induce their formation. In muscle, synapses occur at sites of high receptor density³³⁻³⁵, although membrane components other than the receptor are probably required for synapse formation³⁶ and recognition³⁷, as well. The proliferation of extra-junctional ACh-R that occurs in muscle after transmission block with α -BTX is significantly less than that which occurs following denervation³⁸, and is primarily related to disuse³⁸⁻⁴⁰. Since, in the present experiments, tectal cells treated with α -BTX were still driven by other inputs, there may have been relatively little stimulus of new receptor synthesis⁴¹. If synapse formation in CNS neurones requires a region of high receptor density, these results suggest that the proliferation of new ACh-R on receptor-blocked cells is slow with respect to the dynamics of the sprouting mechanism. Although the latter seems likely to involve a change in the sequence of gene activation in the ganglion cell nucleus, the expression of which will be delayed by the time required to transport materials between the cell body and its axonal terminals⁴², sprouting is known to occur rapidly in other systems in response to denervation⁴³.

It is possible that the stimulus for the apparent growth of terminals back into the toxin-treated zone occurred as a result of factors independent of the cells there (for example, crowding, non-optimum matching of molecules on pre- and postsynaptic elements, functional mismatch of information carried by displaced terminals, or a spontaneous tendency to sprout). Conversely, the question arises as to whether the re-establishment of the original pattern of terminals after toxin application is associated with the appearance of unbound receptors. The latter would be brought about by loss of toxin due to dissociation and proteolysis, and by receptor turnover, in addition to any stimulated increase in synthesis. Kouvelas and Greene⁴⁴ measured a half life of 5.1 h for α -BTX-ACh-R complex in synaptosomal fractions of chick optic tectum. A half-life of 26 h was obtained in synaptosomal fractions of toad optic tectum, using similar techniques (R. Oswald and J.A.F., in preparation). Toxin-receptor dissociation in subcellular fractions may differ significantly from that in the intact membrane, due to possible alterations of the normal molecular interactions affecting receptor conformation⁴⁵. Light autoradiographs made one week after ^3H - α -BTX application in toad tectum still showed a distinct trilaminar pattern of silver

grains (J.A.F. and W. A. Lutin, in preparation) corresponding to the distribution of retinal terminals⁴⁶. This would suggest that toxin-receptor complex is more stable *in situ* than in membrane fractions, and that its removal is slow. The turnover rate of ACh-R in brain has not yet been measured, although Lajtha *et al.*⁴⁷ have shown that 94% of membrane proteins (presumably including ACh-R) labelled with ^{14}C -tyrosine had a mean half life of 10 d. The above observations suggest that the effects of α -BTX are likely to persist for several days.

If re-ordering of retinal terminals in Fig. 6c is associated with the molecular dynamics of ACh-R, how is information about the state of surface receptors communicated to the displaced terminals? Either some terminals must remain in the toxin-treated zone allowing for direct communication, or the cells there must liberate (or fail to liberate) some factor, sensed by the displaced terminals, which affects their growth. It is possible that some trophic factor, metabolically linked to the synthesis of ACh-R, is involved in the re-ordering of synapses.

If these ideas are correct then the receptor protein might have a role in determining the postsynaptic cell's own innervation. Although the acetylcholine receptor apparently does not have a critical role in the molecular recognition or initial formation of synaptic sites, it does seem to have such a role in their maintenance, and might participate in structuring the patterns of synaptic connections.

This work was supported by NIH Career Development Award EY70240 and National Eye Institute grant EY01117. I thank W. Lutin, R. Oswald, R. Brady, J. Norden, and members of the Department of Physiology, NIMR, Mill Hill, London, for their help.

letters to nature

Observations of OE323(4C34.13), MO758+120, and OS210(4C28.40) with the 5-km telescope

FOUR extended radio sources identified with quasars of large redshift have been observed¹, they are important in defining the relationship between mean radio angular diameter and redshift and thus limiting the permissible range of q_0 and cosmological evolution of the radio source population. A difficulty with such analyses is that of allowing for the variation of the physical sizes of individual sources with time, particularly if there are different types of source present in the sample. The ideal would be to restrict the analysis to a single type with a comparatively small range of the relevant properties. We have, therefore, mapped three of the four sources—those accessible to the 5-km telescope—in order to study their structures with greater angular resolution and a better beam shape. We have also re-measured the optical positions of the associated quasars from the prints of the Palomar Sky Survey. Our results remove the positional discrepancy for MO758+120 (ref. 1) and confirm the association of an optical quasar with each of the radio sources. The suggestion that the optical and radio positions of MO758+120 (ref. 3) had been accidentally interchanged seems to be

incorrect, since our optical position agrees with that given by Baldwin *et al.*³ to within 0.25 arc s.

Our observing frequency was 2.7 GHz, as used by Gearhart and Pacht¹, and the beam size (FWHP) $3.7 \times 3.7 \cos \delta$ arc s; in one case, OS210, the source had previously been mapped at 5 GHz (ref. 2) with a beam size 2×4.1 arc s.

Figure 1 shows the 2.7-GHz maps in which the declination scales have been compressed so that the beams seem circular; one can then more easily detect the presence of marginally resolved components. The peak positions and flux densities of the components are given in Table 1. In the case of OS210 no central nuclear component was found, and our observations at 5.0 and 2.7 GHz may be combined with measurements of the total flux density at other frequencies to obtain a mean spectral index for the two outer components. The other two sources are found to be triples, in one of which the nucleus provides most of the flux at 2.7 GHz. To estimate the spectra of the outer components of each, an attempt was made to correct the measurements of total flux density, which are available over a wide range of frequency, by subtracting the flux density attributable to the 2.7-GHz nucleus on the assumption that its spectrum is flat. Details for the individual sources follow.

A weak central radio component lies within about 1 arc s of the optical quasar OE323, confirming the identification. The

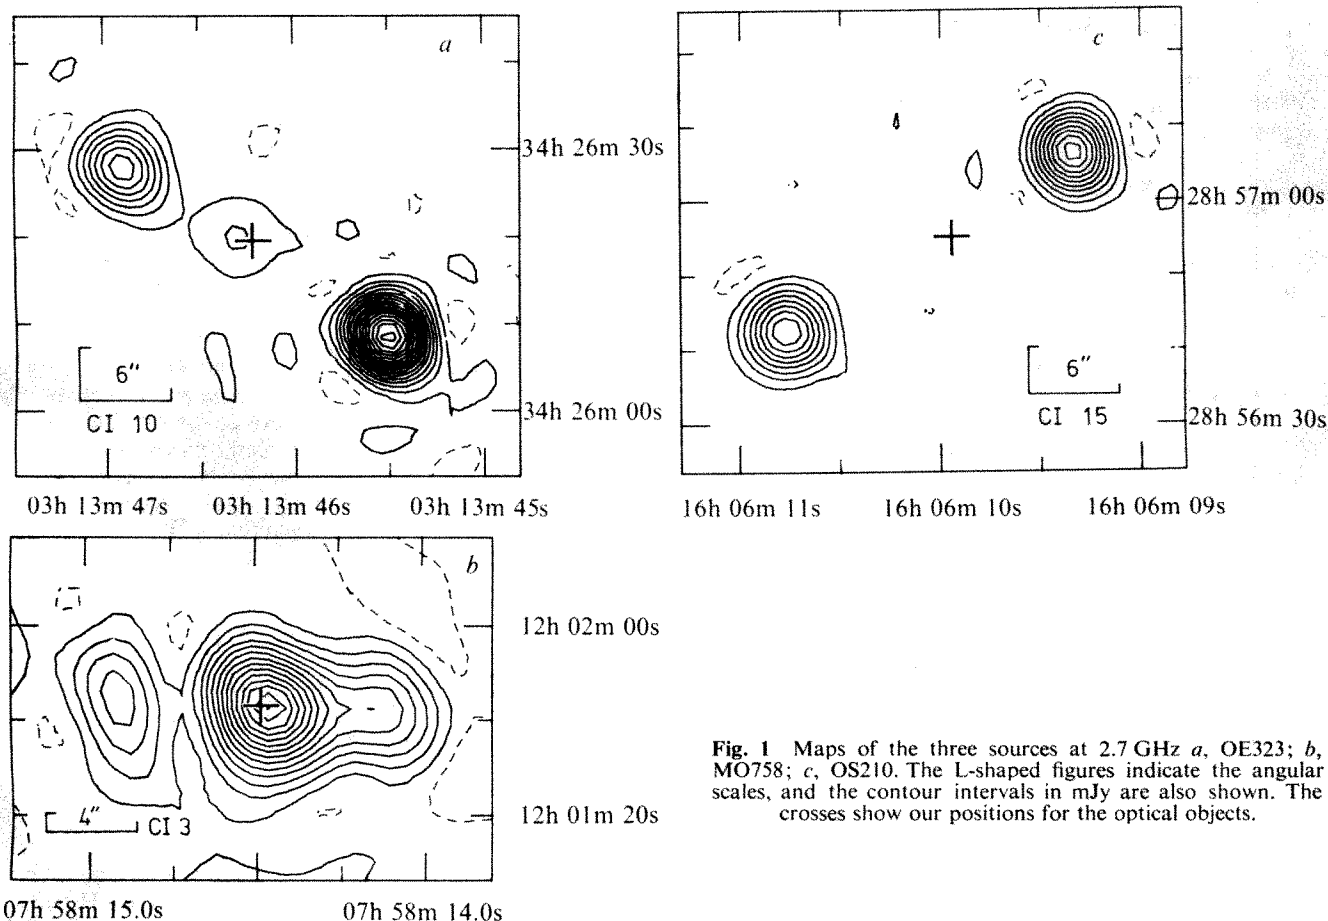

Fig. 1 Maps of the three sources at 2.7 GHz a, OE323; b, MO758; c, OS210. The L-shaped figures indicate the angular scales, and the contour intervals in mJy are also shown. The crosses show our positions for the optical objects.

Table 2 Physical extent, total intrinsic luminosity and the relative luminosity of the nucleus to the total

Source	z	θ (arc s)	$S_{2.7}$ (mJy)	D (kpc)	$\Omega = 0$		$\Omega = 1$		$\frac{P_N}{P_{\text{Total}}}$	α_{outer}
					$(10^{26} \text{ W Hz}^{-1} \text{ sr}^{-1})$	P_5 ($10^{26} \text{ W Hz}^{-1} \text{ sr}^{-1}$)	D (kpc)	P_5 ($10^{26} \text{ W Hz}^{-1} \text{ sr}^{-1}$)		
OE323	1.156	26.2	282	299	1.8	225	1.0	0.04	0.96	
MO758+120	2.66	11.3	66	152	4.1	86	1.3	0.34	1.43	
OS210	1.989	31.1	320	401	9.0	255	3.7	<0.01	0.92	

spectral index of the unresolved outer components over the range 178 to 2,695 MHz is $\alpha = 0.96 \pm 0.05$ (defined by $S \propto \nu^{-\alpha}$).

The source MO758+120 is a well-defined triple with a very powerful central component; our optical position for the quasar lies within about 0.7 arc s of the central component. Gearhart and Pacht's observation did not resolve the source, and indicated a positional difference of some 16 arc s between the radio centroid and the optical identification. The spectrum of the outer components can be derived from our 2.7-GHz results and low-frequency observations for which the correction for the nucleus is small. Over the range 38–2,695 MHz the spectrum is very steep with $\alpha = 1.43 \pm 0.02$.

OS210 is a double with unresolved components, our optical position lying within 0.8 arc s of the line joining the components. The earlier 5-GHz map shows both components to have angular sizes less than 2 arc s. Over the range 38–2,695 MHz, $\alpha = 0.94 \pm 0.02$.

In order to compare the physical characteristics of these sources, the physical extent, the total intrinsic luminosity (P) and the relative luminosity of the nucleus to the total for each were computed for the Einstein–de Sitter ($\Omega = 1$), and Milne ($\Omega = 0$) models (Table 2). To reduce the uncertainty arising from the spectrum of the nucleus, these values are extrapolated to 5 GHz, which corresponds more closely to the mean frequency of emission than to that of observation of 2.7 GHz.

It can be seen that even amongst these three sources there is a wide spread in projected diameter, luminosity and morphological type and, in attempting to distinguish between different cosmological models (including the type of source evolution involved), it will be necessary to take account of more source parameters than have been considered hitherto. The results emphasise the importance of high resolution and high sensitivity in the study of these problems.

We thank the director of the Institute of Astronomy for the use of the x-y measuring machine. M.A.C.P. thanks the SRC for a maintenance award.

Reducing greenhouses and the temperature history of Earth and Mars

THE modern theory of stellar evolution implies that the Sun has increased in brightness by several tens of per cent over geological time. Were all other global parameters held constant, this would imply that the mean temperature of the Earth was below the freezing point of seawater about 2×10^9 yr ago¹. There is, however, excellent geological and palaeontological evidence that there were extensive bodies of liquid water on the Earth between 3 and 4×10^9 yr ago. A possible solution to this puzzle, first postulated by Sagan and Mullen¹, is that the Earth's primitive atmosphere contained small quantities of NH_3 and other reducing gases which significantly enhanced the global greenhouse effect. NH_3 is especially effective in the 8–13 μm window in a CO_2 – H_2O atmosphere. It was argued that plausible changes in other global parameters, such as the infrared emissivity or the Russell–Bond albedo, would have been ineffective. The increase in solar brightness over geological time seems model-invariant even under extreme model perturbation for the solar interior¹, as has recently been reconsidered in a straightforward stellar structure scaling argument². Cosmochemical considerations point strongly to a higher abundance of reduced constituents in the primitive than in the contemporary terrestrial atmosphere; and reduced atmospheric components such as NH_3 and CH_4 are required to understand the accumulation of prebiological organic compounds necessary for the origin of life in this same period, between 3 and 4×10^9 yr ago³.

The calculations of Sagan and Mullen used a very simple square-wave opacity model, and radiative equilibrium. The model predicts the correct value of the present terrestrial global temperature (about 288 K). Calculations were carried out for three primitive atmospheres, as shown in Fig. 1: (1) a high-density hydrogen-rich primitive atmosphere where the opacity was provided primarily by pressure-induced dipole and forbidden quadrupole transitions of H_2 ; (2) a hydrogen-poor, but still reducing, primitive atmosphere in

Fig. 1 Evolutionary tracks showing the time evolution of global surface temperatures of the Earth for three different atmospheric chemistries¹. The arrows for Swaziland and Bulawayan rocks indicate two of several lines of evidence for extensive liquid water in the early history of the Earth. The points show recent measurements of surface temperatures from isotopic thermometric techniques⁴. The bolometric Russell-Bond albedo is taken as 0.35. Time is measured in aeons (1 aeon = 10^9 yr).

which the opacity was provided primarily by the chemical equilibrium abundance of ammonia ($\sim 10^{-4.5}$ volume mixing ratio); and (3) a hydrogen-depleted atmosphere in which the ammonia abundance was subequilibrium, due primarily to the photodissociation of NH_3 . The time dependence of these opacities was determined crudely, allowing for Jeans escape of hydrogen from the exosphere and the subsequent oxidation of reducing compounds, with a characteristic period $\sim 3 \times 10^8$ yr.

Knauth and Epstein⁴ have obtained, through $\text{D}/^{18}\text{O}$ isotopic archeothermometry, data on mean global temperatures from the present back to about 3×10^9 yr ago. These points are also shown in Fig. 1 and roughly parallel the high opacity evolutionary tracks (either 1 bar H_2 and equilibrium NH_3 , or equilibrium NH_3 alone), and provide some support for the idea of a substantial primitive greenhouse effect described in (1) above. Since the observed temperatures seem a little higher than the tracks calculated, it seems useful to point out that octopole transitions of methane, neglected in (1), have been shown by Pollack³ to

be significant for the greenhouse of Titan. If a primitive terrestrial atmosphere with total pressure ~ 1 bar had more than ~ 0.01 CH_4 , the CH_4 opacity would have made an important contribution to the greenhouse effect. Even if the NH_3 opacity were overestimated in (1), CH_4 and NH_3 together as minor constituents in the primitive terrestrial atmosphere seem capable of explaining in a very natural way what otherwise would be a serious discrepancy between astrophysical theory and geological observation.

The same computational protocol has been applied to the evolution of surface temperature on the planet Mars. Results are shown in Fig. 2, for two possible bolometric Russell-Bond albedos of Mars, 0.15 and 0.30, and for three conceivable early compositions: (1) a 1 bar H_2 atmosphere; (2) a 1 bar H_2 -depleted early atmosphere with NH_3 as a minor constituent; and (3) a low-pressure early atmosphere, comparable to the present martian atmosphere, in which CO_2 and small quantities of water vapour provide the principal sources of infrared opacity. Three separate Viking instruments have determined the abundances of trace

Fig. 2 Evolutionary tracks for the time dependence of surface temperature for Mars for three early compositions and two different bolometric Russell-Bond albedos.

isotopic constituents in the contemporary martian atmosphere, and have been interpreted, by a set of independent arguments, to indicate a possible higher pressure atmosphere in early martian history⁶⁻⁸. The most frequently cited estimates of total pressure are about 0.1 bar, but estimates range as high as 1 bar. Because of the low exosphere temperature, H₂ does not escape from Mars today significantly faster than it does from Earth, despite the larger gravitational acceleration of the latter.

The results indicate that if primitive Mars, like primitive Earth, had even a mildly reducing atmosphere, martian global temperatures a few times 10⁹ yr ago may have been in the vicinity of the freezing point of seawater and, in many latitudes, the mean temperatures may have been above the freezing point. This result is of possible interest for the martian sinuous channels, many of which seem to be produced by aqueous fluvial erosion and which have been crudely dated by cratering statistics techniques as having been formed 1–4 × 10⁹ yr ago⁹⁻¹⁵. Although the Viking imaging and microbiology experiments have so far yielded no unambiguous evidence for martian biology¹⁶⁻²⁰, the implication of this work—that in earlier martian history, temperatures and pressures may have been substantially higher in a reducing atmosphere and extensive bodies of liquid water present—certainly enhances significantly the *a priori* likelihood of the origin of life on early Mars. Of course, even if life arose, there is no guarantee that it survived subsequent inclemencies of martian history. Our results also imply, because of the increasing solar luminosity, a very clement martian epoch a few times 10⁹ yr in the future (Fig. 2), when conditions on Earth will become—due to the inexorable nature of stellar evolution—less than ideal (Fig. 1).

This research was supported by the NSF and the NASA. I thank Samuel Epstein and James Pollack for useful discussions, and George Mullen for assistance with the calculations.

Fig. 1 Vertical distribution of the volume mixing ratio of methane in parts per million. The *in situ* sampling results⁹ are shown with the values determined¹⁶ by infrared spectrometry of the P₃ to P₈ multiplets of the 3.3-μm band. The solid curve represents the values used in model calculations⁴. The envelope above 35 km corresponds the methane absorptions at Zenith angle, χ , smaller than 90°.

namely HCl (ref. 5) and ClO (ref. 6). The ratio of their abundances can be expressed by the relation³

$$n\text{HCl}/n\text{ClO} = (k_1 n\text{CH}_4 + k_2 n\text{H}_2 + k_3 n\text{HO}_2) \times (k_4 n\text{O} + k_5 n\text{NO}) / (k_6 n\text{O}_3 + k_7 n\text{OH}) \quad (1)$$

where nA represents the number density of species A and values of k expressed below in cm³ mol⁻¹ s⁻¹, represent the rate constants⁷ of the reactions

The H₂O₂ + Cl → HCl + HO₂ reaction has been neglected due to its low rate constant⁸.

All species in very low stratospheric concentration (except HO₂ which has a minor role) intervening in relationship (1) have been measured—H₂ (ref. 9), NO (refs 10, 11), O (refs 12, 13) and OH (ref. 14). The abundance of ozone is known¹⁵ and most studies have relied on CH₄ data obtained in the stratosphere by *in situ* sampling⁹.

In the altitude range 32–36 km where data are available for computation the $n\text{HCl}/n\text{ClO}$ ratio is observed to be about 0.8 while values ranging from 4.5 to 3.5 result from model calculations⁴.

We have performed a new determination¹⁶ of CH₄ using infrared absorption spectrometry from a balloon platform to give methane mixing ratios over 25 km lower than currently used in stratospheric models. The results, shown in Fig. 1, were derived from spectra of the 3.3-μm CH₄ band obtained simultaneously with HCl absorption spectra¹⁷. They have been used in conjunction with all other measurements to evaluate the $n\text{HCl}/n\text{ClO}$ ratio from equation (1) in order to deduce the effect of these new data on the chlorine–ozone cycle. The

Stratospheric CH₄, HCl and ClO and the chlorine–ozone cycle

SINCE it was suggested¹ that chlorine may influence stratospheric ozone balance, and that halocarbons can contribute significantly to the stratospheric chlorine content²⁻⁴ much attention has been paid to the subject. We report here a new determination of atmospheric methane levels which gives a value lower than that often assumed by other workers. In model calculations this suggests that chlorine has a greater effect on the ozone balance than previously suspected.

In addition to atomic chlorine two main species of the chlorine–ozone cycle have been measured in the stratosphere—

Table 1 Data used in the evaluation of $n\text{HCl}/n\text{ClO}$ and results

	Altitude (km)		
	32	34	36
$n\text{O}_3$ (ref. 15)	2.5×10^{12}	1.9×10^{12}	1.4×10^{12}
$n\text{CH}_4$ (ref. 16)	1.2×10^{11}	7.0×10^{10}	4.2×10^{10}
$n\text{H}_2$ (ref. 9)	2.0×10^{11}	1.4×10^{11}	1.0×10^{11}
$n\text{HO}_2$ (ref. 3)	2.2×10^7	1.9×10^7	1.5×10^7
$n\text{OH}$ (ref. 4)	1.1×10^7	1.1×10^7	1.5×10^7
$n\text{O}$ (ref. 13)	1.3×10^8	2.6×10^8	3.9×10^8
$n\text{NO}$ (ref. 11)	1.3×10^9	1.1×10^9	7.0×10^8
$T(\text{K})$ (ref. 18)	228	234	239
$n\text{HCl}$ (observed) ¹⁷	4.2×10^8	3.0×10^8	2.4×10^8
$n\text{ClO}$ (observed) ⁶	5×10^8	4×10^8	3×10^8
$n\text{HCl}/n\text{ClO}$ (equation (1))	1.2	1.2	0.8
$n\text{HCl}/n\text{ClO}$ (observed)	0.84	0.75	0.8
$n\text{HCl}/n\text{ClO}$ (model) ⁴	4.5	3.9	3.5

number densities used in the computation are listed in Table 1 with the results. The computed values of the $n\text{HCl}/n\text{ClO}$ ratio seem to be in good agreement with observed values while the model calculated ratios are, especially at the lowest altitude, in marked disagreement. Part of this disagreement is due to the use in models of high methane concentrations which have already been considered as being surprisingly large by Wofsy and McElroy¹⁹. A similar opinion has been expressed by Rowland and Molina³ who have considered the possibility of lower methane concentrations leading to an enhancement by a factor of 2 or 3 of the chlorine atom chain.

Thus introduction of high methane concentrations⁹ into model calculations⁴ has lead to a computed $n\text{HCl}/n\text{ClO}$ ratio, for the case considered here, 2.3 times higher than that obtained when using the lower level of methane reported here.

Defects in natural type IB diamond

NATURAL type IB diamond has an anomalously low thermal conductivity. To investigate this we have carried out birefringence, infrared and ultraviolet absorption spectroscopy, electron spin resonance and transmission electron

microscopy (TEM) experiments. We suggest here that the low IB thermal conductivity is due to the presence of previously unknown defects in this type of diamond. It is also suggested that these defects are related to the more common 'platelets' or planar faults which are found in type IA diamond.

The thermal conductivity of IB diamond (specimens C8 and C9 in Fig. 1) was first measured in 1972¹ and subsequent experiments^{2,3} have produced similar results. It was found that the strength of the phonon scattering mechanisms which significantly reduced the IB conductivity as compared to purer IIA diamond, could not be explained solely by the presence of paramagnetic singly substitutional nitrogen atoms^{1,4}. This has now been confirmed to be the case for six IB specimens. A satisfactory theoretical explanation of the original measurements on the basis of Rayleigh-type phonon scattering, could not be found⁴ although the most recent results can be explained if the non-paramagnetic nitrogen (which in this case was more highly concentrated than is usual for type IB) was assumed to be in clusters of several atoms⁵.

We chose for our investigations a transparent amber coloured African diamond (no. 2) from a batch provided by the Diamond Research Laboratory on the basis of extremely low birefringence. Electron spin resonance experiments were performed on this specimen using a Varian E-line spectrometer and a characteristic IB response was observed. Singly substitutional nitrogen atoms are responsible for this behaviour⁵. No attempt was made to calculate the spin density rigorously but it was estimated to be $\sim 10^{23} \text{ m}^{-3}$. Infrared and ultraviolet absorption spectroscopy confirmed that the specimen was a typical IB

Fig. 1 The thermal conductivity of two type IB diamonds, ■, C8 and ●, C9. It is impossible to compute the experimental IB thermal conductivity solely by the addition of a phonon point defect scattering term to that used to compute IIA conductivities.

Fig. 2 The infrared absorption spectrum of diamond no. 2.

diamond⁶ with an average nitrogen concentration of $\approx 6 \times 10^{24} \text{ m}^{-3}$ depending on what fraction of the $1,280 \text{ cm}^{-1}$ absorption was due to A and B centres (Fig. 2). A thin (100) slice was cut and ground from this diamond and studied further by infrared spectroscopy. It possessed a similar concentration of nitrogen to that of the original cube. A selected area of very low birefringence was thinned by ion beam bombardment⁷ to produce a minute perforation, the edges of which were investigated by TEM. This particular diamond thinned perfectly and particularly quickly ($\sim 3 \mu\text{m h}^{-1}$) thereby creating a larger thickness gradient than usual at the edges of the perforation. The large thickness gradient and perfect surface were responsible for the observation of strong 'thickness' fringes by TEM. Small defects showing as black and white dots were seen near the edges of the dark thickness fringes in a bright-field micrograph (Fig. 3). The white dots were seen on the thin side of the dark fringes, the dark dots were seen on the thin side of the light fringes and no dots were seen near the centre of the fringes. In thicker parts of the foil the effective contrast of the dots was reduced because of increased absorption in the crystal. These observations fit the description of the common type of structure factor contrast usually observed when a small inclusion has a lower structure factor than the matrix⁸. It is debatable whether the defects would be detected in the absence of strong thickness fringes. The strain field of the defect seemed spherical although ill-defined under high resolution (0.2 nm point to point) TEM and typically $\sim 5 \text{ nm}$ in size. They are presumably quite homogeneously distributed in the areas which have been observed by TEM. On this assumption, their concentration was $\sim 2 \times 10^{21} \text{ m}^{-3}$ which is a typical 'platelet' concentration in normal IA material. To ensure that the defects were not artefacts the specimen was re-thinned weakly to remove $\sim 10 \text{ nm}$ of the sample surface and further TEM observations were made. This did not alter the appearance of the defects and we feel, therefore, in the light of previous experience of thinning diamond by ion bombardment, that the defects are real. To ensure that the small diamond slice was IB material a further ESR experiment was performed on the slice alone. A characteristic spectrum was observed which indicated that the slice possessed a similar spin concentration to the original cube.

Further detailed investigation by TEM showed that a small number of these minute defects possessed an appearance characteristic of platelets in IA diamond (Fig. 4). The defects were too small and ill-defined for a definite plane to be assigned to them but $\{100\}$ is consistent with the data. It is suggested that these are minute platelets and that the common defect shown in Fig. 3 is the genesis of such platelets. It is unlikely that the minute platelets are

the genesis of these 'bubbles'. If platelets are subjected to high temperatures and pressures, they form larger structures which have some similarities to giant platelets^{7,9}. Other defects seemed to be at an intermediate stage of development.

It is not possible to determine the exact nature of these defects but voids, bubbles of gas or liquid, amorphous material or crystalline material of a low structure factor are all consistent with the results. It is also possible that the defect could be considerably smaller than 5 nm if a strong strain field is present. Some evidence suggests that hydrogen might be present in the bubbles for, of all the diamonds investigated by ion beam spectrochemical analysis, this IB specimen gave the highest hydrogen content¹⁰.

Presumably if the specimen were subject to an appropriate high temperature and pressure environment the bubbles would transform into minute platelets which could then grow up to $\sim 80 \mu\text{m}$ in length^{7,9,11,12}. It should be noted that the common platelets also have a lower effective scattering factor than the diamond matrix¹³.

These defects or bubbles will act as phonon scattering centres and in an interesting fashion. The dominant phonon wavelength in diamond is equal to the bubble size at a temperature $\sim 100 \text{ K}$. Thus for $T \ll 100 \text{ K}$ one would expect a phonon ω^4 -scattering dependence (Rayleigh scattering) to be most important (where ω is the phonon angular frequency) while for $T \gg 100 \text{ K}$ frequency independent scattering would be prevalent. In the intermediate range ($T \sim 100 \text{ K}$) a complex oscillatory scattering mechanism will be most relevant^{14,15}. Therefore, one would not expect the thermal conductivity of specimens C8 and C9 (Fig. 1) to be explained solely by the addition of ω^4 -Rayleigh scattering if they also contained similar defects to those described here. The magnitude of the phonon scattering associated with these particular defects would be sufficiently high to explain the data on C8 and C9. Generally, if the 'bubble' defect size in IB diamond were smaller ($\leq 2 \text{ nm}$) such that Rayleigh-type scattering could adequately describe the phonon defect scattering at all temperatures for which data were available (that is, $T < 300 \text{ K}$), this contribution would be confused with the

Fig. 3 Small defects in a IB diamond showing structure factor contrast. The edge of the specimen is labelled E. Bright-field micrograph. Scale bar $0.1 \mu\text{m}$.

Fig. 4 Small defects in a IB diamond (as used in Fig. 3). Some of these defects appear as minute platelets (P) surrounded by characteristic strain fields. Larger platelets are common in type IA diamond. Scale bar 0.1 μm .

nitrogen cluster scattering mechanism which is identical in its phonon scattering frequency dependence.

We conclude that the thermal conductivity of our sample would be similar to the conductivity of diamonds C8 and C9, and suggest that smaller defects of the same nature might have existed in the other four type IB diamonds for which the thermal conductivity has been measured^{2,3}. It could be that such defects are a general feature of IB diamonds, in which case it would seem that IB diamond is a preliminary state of IA diamond. Synthetic diamond must be the most preliminary state, and a IB diamond will be fabricated if nitrogen is introduced, whereas it has not been possible to synthesise IA diamond¹⁶. If the bubbles contained nitrogen, this would account for the generally higher nitrogen concentration (as detected by infrared) found in IA samples.

Correlation between dielectric constant and defect structure of non-stoichiometric solids

To understand the properties and behaviour of inorganic non-stoichiometric compounds it is vital to know how the stoichiometric imbalance in the material is accommodated structurally. It has been usual to assume that point defect populations have been solely responsible for such departures from the normal stoichiometric formula. But, recent structural investigations have shown that for a growing number of materials this does not seem to be true and instead changes in the anion-cation ratio are accommodated by planar faults. This report points out that an empirical correlation seems to exist between the magnitude of the low frequency dielectric constant of a compound and the structural mode by which it accommodates its non-stoichiometry. Those materials with a low dielectric constant are found to prefer point defect populations, while those with a high dielectric constant prefer planar faults. Some reasons why this correlation should hold are suggested.

Recent studies have mainly led to a recognition of two broad groupings of inorganic non-stoichiometric compounds. First, there are those materials which accommodate stoichiometric changes by way of point defects, either in the classical sense or, in materials with relatively large departures from stoichiometry, by point defect clusters or by ordered arrays of point defects. Examples of this are: Fe_{1-x}O (wüstite), many compounds with the fluorite or fluorite-related structures and the metallic oxides $\text{TiO}_{1 \pm n}$ and $\text{VO}_{1 \pm n}$ (ref. 1).

The second grouping consists of materials in which any stoichiometric variation seems to be taken up by planar faults or intergrowths. In these materials the point defect contribution to the stoichiometric imbalance seems minimal. Instead the structure of the non-stoichiometric crystal can be regarded geometrically as an intergrowth between two phases which have compatible structures, or else as a parent structure which has collapsed along a particular crystallographic plane so as to eliminate one atom type rather than another from the parent matrix. The intergrowth or fault usually takes the form of a lamella only one or two cation-anion polyhedra thick and hence is related to, but differs in scale, from syntaxy.

As these materials are less well known, some examples will illustrate their behaviour and the range of compounds covered. Perhaps the best documented are the crystallographic shear (CS) phases. These are formed when WO_3 , Nb_2O_5 , TiO_2 and other materials are reduced or doped with (generally) lower valance cations. Characteristically they are slabs of the parent higher oxide containing fault planes, the CS planes, which geometrically are planes along which the structure has collapsed to eliminate oxygen. If these faults are ordered, a homologous series of oxides is formed; typical examples being $\text{W}_n\text{O}_{3n-2}$, $\text{Ti}_n\text{O}_{2n-1}$. More examples of CS phases are given in several reviews (refs 1-3 and refs therein.) A second group consists of oxides often described as intergrowths. In these phases, stoichiometric variation is achieved by the ordered or disordered intergrowth of phases with different compositions. Examples are the perovskite-related oxides formed by intergrowth between NaNbO_3 and complex silicate-related phases $\text{Ba}_3\text{Nb}_2\text{Si}_4\text{O}_{26}$ and $\text{Ba}_3\text{Nb}_2\text{Ti}_4\text{O}_{21}$ (ref. 5). Ordered intergrowths can again be expressed in terms of homologous series formulae. Finally, some of the materials described as polytypes can also be placed into this category. Of particular note are the hexagonal ferrites⁶ where structural complexity is associated with intergrowth between units of the spinel structure. The titanium sulphides with compositions lying near to Ti_2S_3

Table 1 Dielectric constant and defect structure type of some non-stoichiometric compounds

Material	Dielectric constant*	Frequency (Hz)	Non-stoichiometry†
FeO	14.2	2×10^6	P.D.

also fall into this group. Stoichiometric variation here can be described as being due to intergrowth between the TiS phase and the TiS₂ phase⁷.

For evaluating materials growth methods, or predicting the chemical or physical behaviour of materials it is valuable to have a reliable guide as to which of these modes of stoichiometric behaviour is likely to predominate in any particular system but at present no such guide has been found.

Calculations of the electrostatic interaction between CS planes in reduced WO₃ (ref. 8) showed that a high value of the low frequency dielectric constant was of importance in reducing this energy term to a small value. The fact that CS planes only seemed to be found in materials which possessed a high dielectric constant was also pointed out by Bursill *et al.*⁹. Taking these two observations as starting points, I have examined the literature in an attempt to determine whether there is a definite correlation between the occurrence of intergrowth as a means of accommodating non-stoichiometry in a material and low frequency dielectric constant. Although the data on both these topics are scanty a very good correlation is found, provided that those materials in which a high value of the low frequency dielectric constant is associated with hydrogen bonding are excluded, as the crystal-chemical relationship between dielectric constant and structure is rather different in these compounds than in, for example, the perovskite oxides.

Table 1 reports some materials with well known modes of accommodating non-stoichiometry which also have recorded dielectric constant values. Unfortunately data are not available for many interesting compounds, but there are enough to show that systems using point defects have low values of dielectric constant, less than approximately 24, while all the materials with known intergrowth or CS behaviour have values >100 .

In order to apply this empirical correlation usefully it is important to remember that most experiments involving non-stoichiometric behaviour are carried out at moderate to high temperatures. The room temperature dielectric constant which is the value most usually reported and which

is given in Table 1 may well be considerably lower than that at high temperatures, and temperature variation can be large, as in the case of WO₃ (ref. 12). Thus for some materials, a change in behaviour with temperature may be expected, MoO₃ may be such an example¹⁷.

In the non-metallic materials we are considering, the low frequency dielectric constant is composed of two components, the electronic and ionic polarisabilities of the atoms in the structure. A high value of the static dielectric constant is often attributable to a high ionic polarisability term, which is largely due to the presence of small off-centre cations in metal-oxygen coordination octahedra which form the building units of many oxides. The ferroelectric perovskites fall into this class. In other materials, such as PbS or SbSI the presence of large easily polarisable anions and lone pairs of electrons on the cations produces large electronic polarisation. Neither of these features in themselves, however, seem to explain why a point defect population should be resisted in these materials, although recent lattice energy calculations for materials containing point defects have shown that polarisation terms have a considerable effect on defect formation energies.

A possible reason for the rejection of high point defect populations may be found by considering the lattice dynamics of crystals. The low frequency dielectric constant of a crystal and hence the ionic and electronic polarisabilities of the component atoms are closely connected with the allowed lattice vibrations of the matrix. The simplest form this relationship takes is expressed by the Lyddane-Sachs-Teller relationship which shows that a high static dielectric constant is associated with a transverse optical phonon, ω_T , of very low frequency in the lattice¹⁸. These soft transverse modes are temperature dependent and tend to exhibit instability as the frequency falls, that is, as the dielectric constant increases. Barker¹⁹ has shown that soft mode instability can be strongly influenced by the local electric field within a dielectric material. The presence of defects in a material, either some form of point defect arrangement or intergrowths or planar faults, will lead to significant changes in the local fields in some regions of the crystal which will have a bearing on the stability of the soft ω_T modes. The interaction will almost certainly be complex and has not been analysed quantitatively, but it seems reasonable to suggest that in materials with a high dielectric constant the existence of potentially unstable soft ω_T modes favours the formation of sheets of defects, intergrowths or crystallographic shear planes, over point defects or point defect clusters.

The lack of a detailed theoretical treatment, together with the paucity of experimental data make these suggestions very speculative. Despite these qualifications the empirical correlation between dielectric constant and defect structure seems to work well and be useful. It provides a guide to the structural behaviour of non-stoichiometric solids where none has existed before. Theoretical studies are now underway which, it is hoped, will provide a more quantitative understanding of the problem. In particular it is important to determine the extent to which there may be a causal relationship between low frequency dielectric constant and the mode of accommodation of non-stoichiometry which, at present, is by no means certain.

Crystal structure of rustumite

RUSTUMITE was first described by Agrell¹ as $\text{Ca}_4\text{Si}_2\text{O}_7(\text{OH})_2$, space group Cc or C2/c, $a = 7.62(5)$, $b = 18.55(5)$, $c = 15.51(5)\text{\AA}$, $\beta = 104^\circ 20'(10')$, with $Z = 10$. The crystal structure we describe here, in space group C2/c ($R = 11.3\%$ for all data) gives, instead, an ideal formula $\text{Ca}_{10}(\text{Si}_2\text{O}_7)_2\text{SiO}_4\text{Cl}_2(\text{OH})_2$, with $Z = 4$. The important features of the completed structure are the presence of chlorine and of orthosilicate groups in addition to Si_2O_7 groups.

The experimental intensity data, from a naturally occurring single crystal, comprised 2,100 independent reflections for layers 0–9, k, l ($\sin^2\theta < 0.2$) obtained with a Hilger and Watts Y-190 linear diffractometer and Mo-K α radiation, using the cell dimensions given by Agrell¹. Of this data, 282 reflections were classed as 'unobserved', and were excluded from all further calculations.

Solution of the Patterson map was hindered by the large number of atoms in the unit cell (~ 150), permitting the detection of only four (or more)-multiple peaks, and the presence of subtranslations of $\sim a/4$, $\sim b/6$ and $\sim c/6$ among the Patterson

Fig. 1 Rustumite—(010) projection of one half of the unit-cell. The Si_2O_7 and SiO_4 groups are indicated as polyhedra. The Ca atoms overlap in pairs: ●, (Ca1, Ca1'), (Ca4, Ca5); ○, (Ca2, Ca3).

peaks. Nevertheless, an initial structure was established in the space group C1 by double superposition using two multiple peaks as shift vectors² and consideration of the vector subsystem³.

In the course of refinement by the usual Fourier methods, as the remaining atoms of the structure appeared, the presence of first the twofold axis and finally the c -glide became obvious. The final solution in the space group C2/c, refined by block diagonal least squares using all of the observed reflections except 171 which showed especially poor agreement between F_o and F_c , gave the parameters of Table 1. At this stage R was 7.4% for the data included in least squares (11.3% over all observed data).

In the asymmetric unit it is easy to pick out, apart from the five Ca atoms, an $(\text{Si}_2\text{O}_7)^{6-}$ group (involving Si1 and Si2) and an $(\text{SiO}_4)^{4-}$ group involving Si3 on a twofold axis (Fig. 1), leaving only O10 and O11. The atom O10 yields a peak in the electron density maps comparable in size with Si3, gives an occupancy factor (refined as oxygen) of ~ 2.0 in least squares refinement and has no nearest-neighbour Ca atom closer than 2.75 Å, all consistent with this atom being Cl. Bogomolov and Organova (personal communication) have given analytical data for chloride in rustumite.

Whereas all other O atoms, including O10, are four-coordinate, O11 has only three Ca nearest neighbours (Ca—O, 2.33–2.37 Å) all to one side of it, clearly allowing completion of its tetrahedral coordination by a hydrogen atom. Therefore, although there is no clear evidence for the H atom in the electron density or difference maps, O11 can reasonably be regarded as a hydroxyl group to give the formula $\text{Ca}_5(\text{Si}_2\text{O}_7)(\text{SiO}_4)_{0.5}\text{Cl}(\text{OH})$ for the formula of the asymmetric unit (eight per cell) of rustumite. The cell contents are then $\text{Ca}_{40}\text{Si}_{20}\text{O}_{72}\text{Cl}_8(\text{OH})_8$ compared with $\text{Ca}_{40}\text{Si}_{20}\text{O}_{70}(\text{OH})_{20}$ from Agrell's formula.

We thank Professor H. F. W. Taylor for bringing this problem to our attention and the SRC for a grant to V.V.I.

Imaging practical surfaces in a field ion microscope

APPLICATIONS of the field ion microscope (FIM), have been restricted probably because of the need for specially prepared specimens. We present here, for the first time, experimental data on imaging practical surfaces with the FIM. This should provide more applications for this instrument especially in studying multi-protrusions or whiskers.

The techniques used in the FIM including the vacuum system are conventional. In the first stage of the experiments, we tried imaging multi-tips from a single tip holder. Surprisingly, we could identify the individual images of the single tips, and these were geometrically superposed. The images of twin tips of tungsten are shown in Fig. 1a. Figure 1b shows a simulated pattern obtained by superposing two negatives of a single tip image of tungsten. The close correspondence between the two patterns is striking. This imaging was repeated for three and so on up to seven tips. In each case it was possible to get the resolved images although their stability was poor because of the unavoidable differences in specimen tip size, shape and relative displacements, all of which led to a vast difference of field concentrations about each tip.

Fig. 1 a, Twin tips of tungsten imaged. b, Superposed images of two tungsten tips. Voltage, 17 kV.

In each case, another striking observation was made after the tips were blunted by rapid field-evaporation. Even at the highest voltage of 28 kV (limited by our high voltage unit), no resolved image could be seen. In all these cases, however, the image pattern exposed bright circles—usually rings with haloes around them—the number corresponding to the number of multi-tips mounted for the projection (Figs 2, 3). Using scanning electron microscope (SEM) patterns for these tips, and assuming an approximate field-factor, the magnification for these tips was estimated and a good experimental fit was observed. But the reason for

Fig. 2 Image of four tips depicting four rings. Voltage, 25 kV.

these bright ring images is not clear. As tips were blunt, the available voltage was probably insufficient to obtain best imaging voltage (BIV) with helium gas. All imaging was done at background pressure of 10^{-6} torr or less. At the liquid nitrogen temperatures at which our voltages were applied, nitrogen and other residual gases probably reached the tip by surface migration along the shank¹, and then field-

Fig. 3 Image of seven tips depicting seven rings. Voltage, 42 kV.

evaporated. Did the dimension of the ring, then, represent the tip diameter? If the relative displacements of these tips could be assumed, then these images would help trace the electric field contours and field-factor determination for these complex conditions. At times, one could even observe very strange cross lines (Fig. 4) which can only be understood as representing the arc of field distribution which

Fig. 4 Cross lines depicting potential profile. Voltage, 45 kV.

would be too complicated to map for the multiple tips case where equipotential overlappings are expected.

In a later experiment carried out on three tip specimens, an interesting feature was observed. After the first flashings and bluntings of the tips, one microprotrusion, probably belonging to one of the blunt tips became very well resolved at a voltage of 32 kV. When the imaging gas helium was cut out, the resolved tip image disappeared completely leaving the surrounding random adsorption pattern unchanged (Fig. 5*a, b*). This resolved image could also be field-evaporated later atom by atom in a controlled fashion until the image completely vanished. The protrusion size calculated from the evaporated rings was 21 Å.

Our most interesting results were obtained when a good low voltage single tip (Fig. 6) slipped and fractured during rapid field-evaporation. On raising the voltage, distinct circles were seen (Fig. 7), representing different microprotrusions created on the main tip by the fracture. One ring was seen as distinctly separated from an overlapping group (estimated to be four) of rings. At a higher voltage,

Fig. 5 *a*, Image of deformed tip without imaging gas. *b*, Image of the same tip with helium gas. Voltage, 32 kV.

~41 kV, this group of overlapping rings resolved (Fig. 8) and at least one well defined symmetric tungsten image could be clearly detected. This microprotrusion could be clearly field-evaporated and imaged without any interference. The radius of the original tip was calculated using both Bowkett's² and Müller's³ methods and a value of 220 Å was obtained. By a similar method, the radius of the microprotrusion was calculated to be 35 Å. Using Rose's⁴ formula for magnification enhancement for a conducting protrusion on a field emitter, we calculated the magnification expected for our micro-tip and, finally, its image diameter as observed on the screen. The calculated diameter was about 4 cm and the experimentally observed image was a ring 3.7

Fig. 6 Single tip of tungsten. BIV, 9.8 kV.

cm in diameter. The SEM pattern taken at the end of this experiment did not indicate the presence of a protrusion. This renders our technique more sensitive for the detection of such extremely small protrusions unresolved by other microscopic techniques available.

Fig. 7 Tip of tungsten (the same as in Fig. 6) after a flash. Voltage, 18 kV.

To conclude, it is possible to resolve individual microprotrusions of a few tens of ångströms on a practical surface using the field ion microscope.

Further it seems feasible to (1) map equipotentials for complex distribution of conducting protrusions on a surface and calculate field factors which hitherto was not possible;

Fig. 8 Resolved microtip. Voltage, 43 kV.

and (2) image simultaneously and without mutual interference, dissimilar elements that can be grown as microprotrusions or whiskers. This will enable us to understand specific sites on the substrate for nucleation, in relation to crystallographic features and so on. The atom probe³ coupled to this mode of operation of FIM will permit us to chemically identify individual atoms from different protrusions.

We are grateful to the late Dr D. Y. Phadke who encouraged this unconventional approach.

Archaeological evidence for Subrecent seismic activity along the Dead Sea–Jordan Rift

EXAMINATION of archaeological sites and records in the Levant reveals features of destruction attributable to ancient earthquakes, which may help in verification of old earthquake catalogues and in assessment of seismic hazards.

Regional seismicity in Israel is characterised by sporadic shocks of up to $M=7$, separated by long quiescent periods. The shocks, believed to originate mainly along the Dead Sea–Jordan Rift, where microtremors occur also during the quiescent periods, are documented by instrumental and historical data^{1–7}. Historical earthquake evidence, however, is based on biblical, ecclesiastical and historical chronicles, which are tainted by superstition, exaggeration and misinterpretation of natural phenomena. Consequently, the estimates of incidence, intensity and distribution of individual shocks presented by different cataloguers differ considerably^{1–6,8,9}.

To obtain material evidence¹⁰, we have examined the record of archaeological excavations in Israel, searching for reports of catastrophic damage at explored sites. Summaries of archaeological findings^{11,12} and responses to questionnaires circulated among Israeli archaeologists revealed numerous cases in which destruction and desertion were attributed to major earthquakes (Table 1). Field examination of the reputed features of seismic damage (for example, joints, cracks, faults and breakage; tilted and distorted walls, buildings and aqueducts; oriented collapse and subsidence; and parallel alignment of fallen columns and masonry) showed them to be less unequivocal than generally assumed by archaeologists, because very similar effects may be caused by poor construction or unfavourable geotechnical conditions, unrelated to any seismic events. At the same time, it seems that these 'earthquake indicators' were used by archaeologists fairly consistently, and that the assignment of such features of architectural damage to seismic shocks at

any individual site, though probably prejudiced by interpretation of historical records, was unbiased by previous geological or geotechnical considerations.

Of all the excavated pre-1000 AD (pre-Crusader) sites, which are fairly evenly distributed over northern and central Israel, although sparser in the more arid south, we plotted in Fig. 1 only those where excavations uncovered building elements of extent and quality sufficiently high for features of architectural damage not to pass unnoticed. On the same map we marked all the sites with supposed seismic damage. The shock-affected sites differ in lithological and topographical setting, and most of them are located along the Dead Sea–Jordan Rift and its margins. This concentration (about 75%) is greater than that indicated in the historical catalogues (15–30% of references mention the Rift zone). The present distribution of these sites does not show whether they are located along the major Rift faults or along subsidiary crescentic faults and blocks or both. It

Bacterial sulphate reduction and calcite precipitation in hypersaline deposition of bituminous shales

BITUMINOUS shales of the Ghareb Formation of Maastrichtian age from Nebi Musa (near Jericho, Jordan Valley) were analysed for their texture, mineralogical and chemical composition. The results from the lowermost bed of the formation are of broad interest, and indicate special diagenetic processes affecting sediments rich in organic material deposited in an anaerobic hypersaline environment. Single crystal calcite replacement of gypsum infilling of foraminifera and a predominance of even over odd carbon numbers among C_{25} – C_{30} *n*-alkanes indicate sulphate reducing bacterial activity during deposition of bituminous shales in a hypersaline environment.

The samples taken consist of hard black calcareous shale with up to 15% organic carbon, containing also kaolinite, detrital phosphate and pyrite. Foraminifera constitute a major component—particularly thin walled, small plank-

Fig. 1 Scanning electron micrographs of calcite replacement of gypsum infilling of foraminiferal tests. *a*, Chamber filled with gypsum (pitted surface) and a calcite crystal growing in its centre. Scale bar 5 µm. *b*, Chamber partially filled with a euhedral single calcite crystal. Scale bar 5 µm. *c*, Foraminifera completely filled with single calcite crystals. tonic ones. The benthonic foraminiferal fauna is composed exclusively of numerous specimens of Buliminidae of one or two species only. Exclusively benthonic Buliminidae assemblages occurring in the phosphates of the underlying Mishash Formation were interpreted as indicating semi-closed, near-shore basins with low surface salinity and oxygen deficiency¹. The addition of abundant planktonic foraminifera to the Buliminidae assemblages in the Ghareb Formation may indicate a change of salinity in the surface waters. The organic matter (mostly kerogen) is dispersed and no structure indicative of its source can be observed even in the scanning electron microscope (SEM).

A mineralogical investigation using petrographic microscopy, X-ray diffraction and microprobe analysis revealed that the foraminiferal tests are filled with either of the following minerals: gypsum, single crystals of calcite, and pyrite, which is also dispersed in the matrix. The calcite infilling in the form of a single crystal in a foraminiferal chamber or a whole test was observed optically under the petrographic microscope and morphologically in the SEM. Locally, stages in the replacement of gypsum by single crystal calcite growth can be observed with the SEM (Fig. 1*a*), as well as steps towards complete single crystal calcite infilling of a foraminiferal test (Fig. 1*b*, 1*c*). This infilling cannot be regarded as a late diagenetic sparry calcite mosaic from which it differs in texture. Moreover, sparry calcite development through dissolution and precipitation is not likely to have taken place in the impervious shales.

The samples from the lower Ghareb Formation showing these mineralogical features also exhibit particular organo-geochemical markers, especially with regard to the *n*-alkanes extracted. There is a high concentration of *n*-C₁₉ alkane and a prominent envelope in the C₂₆–C₃₂ carbon number range, in which even carbon number C₂₈ and C₃₀ predominate over their odd carbon number homologues (Fig. 2*b*). This *n*-alkane distribution differs from that of living and fossil higher plants, which are characterised by a prominent envelope in the C₂₃–C₃₃ range, with a marked odd over even preference^{2,3}, as well as from that of algae and photosynthetic bacteria marked by a higher concentration around *n*-C₁₇ (refs 4–6), such as is found in higher strata of this formation (Fig. 2*a*).

Even over odd preference in the C₂₆–C₃₂ range in rock extracted *n*-alkanes was attributed to highly saline environments mainly on the basis of local geological and sedimentological considerations^{7,8}. Studies of the *n*-alkane content of algae and bacteria grown in the laboratory showed that non-photosynthetic anaerobic bacteria have a high concentration of *n*-C₁₉ and longer chain alkanes^{4,5}. An even over odd preference in the C₂₆–C₃₂ range of *n*-alkanes was reported from cultures of *Desulfovibrio hildenboroughi*⁴, a common sulphate reducing bacterial species. It seems, therefore, that the *n*-alkane distribution of the samples investigated is indicative of contributions from both anaerobic, non-photosynthetic, as well as sulphate reducing bacteria.

The palaeontological and sedimentological record of the lowermost beds of the Ghareb Formation, the occurrence of gypsum infillings of foraminiferal tests, the single crystal calcite replacement of gypsum, as well as the peculiar *n*-alkane distribution which resembles that of anaerobic and sulphate reducing bacteria, can all be interpreted in terms of environment of deposition and early diagenetic processes as follows.

(1) The bituminous shales were deposited on the bottom of a hypersaline, stratified lagoon, the upper oxygenated, highly productive layer of which was rich in planktonic foraminifera, mainly in the outer part of the lagoon. Organic matter accumulated on the anoxic bottom. (2) Empty foraminiferal tests transported to the inner margin of the lagoon were filled with gypsum either in the upper layer or on the bottom immediately after settling. (3) Anaerobic non-photosynthetic and sulphate reducing bacterial activity resulted in dissolution of gypsum according to the generalised formula⁹

thus increasing the bicarbonate and calcium ion concentration. (4) The waters of the lagoon were already over-saturated with regard to calcium carbonate, therefore, calcite precipitation took place concomitantly where gypsum was dissolved. (5) The presence of pyrite is at least partly due to the production of H₂S during these reactions.

Fig. 2 Gas chromatograms of *n*-alkanes from the Ghareb Formation. *a*, Characteristic *n*-alkane distribution of the bituminous Ghareb Formation; *b*, *n*-alkane distribution of the lowermost bed. Separation on 6 foot $\frac{1}{8}$ inch column packed with 2% Apiezon L on Gas Chrom Z, programming 100–290 °C, 4 °C per min.

The process of single crystal calcite replacement of gypsum infillings of foraminiferal tests, thus envisaged, takes place in a combination of strictly defined conditions: water oversaturated with respect to calcium carbonate and gypsum, in the presence of organic material and sulphate reducing bacteria. It is probable that such replacement is generally indicative of this type of sedimentary environment.

Inducer of pectic acid lyase in *Erwinia carotovora*

PECTIC acid (polygalacturonic acid) lyase (EC 4.2.2.2., PAL) formed in bacteria, catalyses the transesterificative cleavage of pectic acid¹. Because PAL both macerates plant tissues and causes cell leakage and death^{2,3}, it has often been investigated biochemically from the industrial and plant pathological point of view. Physiological studies, however, have been limited, probably because PAL is in part an extracellular enzyme⁴. Thus most studies of its inducibility have compared activities in filtrates of cells cultured on different carbon sources^{5,6}. But assay of an extracellular enzyme does not necessarily reveal changes in its rate of synthesis. In *Erwinia carotovora*, however, the PAL that can be purified from cell-free extracts is probably the same protein as the extracellular enzyme¹. In strain EC-1 of *E. carotovora*, non-induced PAL activity is three to four times greater in cell-free extracts than in the culture filtrate during log phase growth, and the relative rate of increase of intracellular enzyme activity after induction is 130 times greater than the rate of release of PAL into the culture filtrate (unpublished data). I therefore used this strain to study induction by measuring PAL activities in cell-free extracts. I report here that the inducer of PAL in *E. carotovora* may not be pectic acid itself but its breakdown product.

Maximum differential activity has been reported to be in the culture fluid grown on pectic acid⁶. To test this, after the addition of pectic acid into minimal medium of Mikula *et al.*⁷ (without sodium citrate) time course samples were taken, washed, sonicated and assayed by the thiobarbituric acid method⁸. The inducibility of PAL by pectic acid was shown by an increase in PAL specific activity (Fig. 1a). The long lag before the onset of induction, however, suggested that pectic acid was not inducing directly. It is unlikely that the lag simply reflects a low initial rate of uptake of pectic acid because (1) induction was further delayed and a growth lag was observed when pectic acid was added to washed cultures rather than directly to cultures grown in glycerol (Fig. 1a and b) or citrate (data not shown); (2) the lag for the induction by pectic acid was further delayed when 10^{-3} M EDTA was added in addition to pectic acid, and this could be abolished by addition of 10^{-3} M CaCl_2 in addition to EDTA and pectic acid (Fig. 1a). Because Ca^{2+} has been reported to activate many bacterial pectic

Fig. 1 Kinetics of the induction of PAL by pectic acid. *a*, Induction was initiated by the addition of 0.5% pectic acid, pH 8.3, with 10^{-3} M CaCl_2 or 10^{-3} M EDTA, either directly (closed symbols) or after washing (open symbols), to EC-1 cultures grown in minimal⁷ + 2% glycerol medium to A_{655} of about 0.1. At intervals, 6-ml samples were withdrawn, washed twice and resuspended in 1.5 ml of Tris-HCl buffer (0.05 M, pH 8.0). Suspensions were sonicated and the cell debris was removed by centrifugation for 15 min at 10,000g. PAL activity was measured by a modified thiobarbituric acid method⁸. One unit of PAL is defined as the amount of enzyme which produces 1 μmol of UDG per h. Specific activity is expressed as units of enzyme activity per mg of protein. Protein concentrations were determined by the method of Lowry¹⁴. *b*, During the induction experiment growth was measured as the increase in absorbance at 655 nm after the addition of pectic acid. ●, ○, Pectate; ▲, △, pectate + EDTA; ▼, pectate + EDTA + CaCl_2 .

acid lyases (including the *Erwinia* enzyme¹), these two observations suggest that some product of pectic acid degradation by the non-induced level of PAL in culture filtrate is the true inducing metabolite.

The true inducing metabolite of PAL was sought in time-course induction experiments after the addition of one of the purified metabolites of pectic acid into the minimal medium⁷ as a sole carbon source. The major end product of the cleavage of pectic acid by *E. carotovora* PAL is *O*-(4-deoxy- β -L-threo-hexo-pyranos-4-enyluronate)-(1-4)-D-galacturonic acid (unsaturated digalacturonic acid, UDG). The rapid induction was observed specifically when 2×10^{-3} M purified UDG⁹ was added (Fig. 2). Pectic acid is also degraded by hydrolytic polygalacturonase (EC 2.3.1.15., PG) of *E. carotovora*¹⁰. No induction was observed, however, after the addition of galacturonic acid,

Fig. 2 Kinetics of the induction of PAL by UDG. The procedures were the same as in Fig. 1 except that 2×10^{-3} M UDG or 26×10^{-3} M galacturonic acid instead of pectic acid was added after washing the cultures. ●, UDG; ▲, galacturonate.

which is the major product of the cleavage of pectic acid by *E. carotovora* PG (Fig. 2)¹.

UDG is further metabolised to 4-deoxy-L-threo-5-hexoseulose uronic acid by oligogalacturonic acid lyase (EC 4.2.2.6., OGL)^{11,12}, but as the induction of PAL and OGL is uncoordinate in *Erwinia*¹², UDG rather than its further breakdown product is likely to be the true inducer. The inducer, however, might be a product of unsaturated digalacturonic acid formed by way of a minor pathway, as shown with *Escherichia coli* β -galactosidase, where the transfer products of lactose, 1,6-galactosido-glucose and galactosido-glycerol are inducers¹³.

Data concerning other plant pathogenic bacteria and evidence for catabolite repression of PAL will be published elsewhere. Product-induction may well be a mechanism for regulating other enzymes which have macromolecular substrates. The specific inhibition of PAL induction may also provide an approach to the control of plant diseases with non-toxic agents.

I thank Professors N. Okabe and M. Goto for encouragement, Dr C. Hatanaka for UDG, and Drs R. Bigelis, I. Tsujino, T. Mizuno and S. Nasuno for helpful discussions.

Steroids stimulate secretion by insect Malpighian tubules

DURING the growth and development of insects there are rapid changes in the concentrations of the moulting hormones (ecdysteroids). In the locust *Locusta migratoria* the rate of excretion of the moulting hormones is one factor which regulates the ecdysteroid titre^{1,2}. The experiments reported here show that the presence of ecdysteroids causes an increase in the rate of urine production by the Malpighian tubules of the tsetse fly *Glossina morsitans*. Previously there has been no evidence to suggest that steroid hormones are involved in the control of excretion in insects³. These results may therefore indicate both a new function for steroids in insects and a new control system for insect excretory systems.

Teneral adult male flies, 24–48 h after emergence, were used in all experiments. Sections (about 1 cm) of their Malpighian tubules were removed and set up *in vitro* in drops of Ringer solution under liquid paraffin⁴. In the absence of a stimulant the tubules secreted very slowly but the addition of extracts of the thoracic ganglion of the fly (which contains the diuretic hormone⁵) or cyclic AMP caused a rapid increase in the rate of secretion. The high rate was maintained as long as the stimulants were present but rapidly reverted to the unstimulated level when they were removed (Fig. 1). The addition of ecdysone (α -ecdysone) or ecdysterone (β -ecdysone) to the bathing drop also caused an increase in the rate of secretion but the time course of this response was very different from that which was elicited by the diuretic hormone or cyclic AMP (Fig. 1). A delay of 20–40 min occurred between the addition of the ecdysteroid and the commencement of fluid secretion by the isolated Malpighian tubule. After the ecdysteroid was removed the rate of secretion returned to its unstimulated level only very slowly. Where tubules were left in bathing drops con-

Fig. 1 Rate of secretion of a typical *in vitro* preparation of a *Glossina* Malpighian tubule. A tubule was isolated into a bathing drop of Ringer solution, composition (mM) NaCl, 120; KCl, 10; glucose, 20; malic acid, 3; citric acid, 2; $MgCl_2 \cdot 6H_2O$, 2; $NaH_2PO_4 \cdot 2H_2O$, 1.5; $CaCl_2 \cdot 6H_2O$, 2; pH adjusted to 7 with NaOH and phenol red added to keep constant check on pH. The bathing drop was replaced by Ringer containing 10^{-3} M cyclic AMP for the period shown, after which the tubule was returned to basic Ringer before being transferred to Ringer containing 10^{-6} M ecdysone. Finally, the tubule was returned to basic Ringer. Experiments were performed at 25–28 °C.

taining the ecdysteroids they continued to secrete for many hours. At higher temperatures (28–31 °C), though initially the tubules secreted more rapidly in the presence of the ecdysteroids, the preparations deteriorated after 2–3 h and secretion ceased.

Ecdysone and ecdysterone elicited secretory responses of similar magnitudes. Expressed as a percentage of the maximum response of the tubule stimulated by cyclic AMP, 10^{-6} M ecdysone produced a response of $32.7 \pm 7.0\%$ (mean $\pm 2 \times \text{s.e.}$, $n = 8$) and 10^{-6} M ecdysterone a response of $26.3 \pm 3.8\%$ ($n = 5$). Concentrations above 10^{-6} M were found to cause no further increase in the rate of secretion. But, the rate of secretion decreased with decreasing steroid concentrations below 10^{-6} M, down to a threshold response at 2×10^{-8} M. The response of the tubules at these low concentrations indicates that they would be stimulated to secrete by ecdysteroids at the concentration which is present in the haemolymph of teneral adult male *Glossina*. This was estimated by radioimmunoassay to be 375 pmol g^{-1} . Whole insect extracts of teneral male flies of the same age contained $203 \pm 38 \text{ pmol g}^{-1}$ (mean $\pm 2 \times \text{s.e.}$, $n = 12$; unpublished observations of D.L.W.). Approximately half the total ecdysteroid content of the fly is therefore present in the haemolymph. Whole fly extracts assayed by radioimmunoassay have shown a concentration of 600 pmol g^{-1} in adult male *Calliphora* (J.K. unpublished observations) and the concentration of ecdysterone in adult male *Drosophila* measured by gas-liquid chromatography (350 pmol g^{-1} fresh weight) is in fact higher than at any other stage of its life cycle⁶. It has been known for some time that ecdysteroids are present in adult insects⁷. In female *Locusta*⁸ and *Bombyx*⁹ they are present in the ovaries and oocytes but previously there has been no hormonal function attributed to the high concentrations of ecdysteroids in adult male insects.

The rates of secretion of Malpighian tubules in Ringer's solution alone, in Ringer containing ecdysteroids and in Ringer containing other biologically active steroids are compared in Table 1. In all cases a delay between the introduction of the steroid and the commencement of secretion occurred (range 20–80 min) and the return to the base rate of secretion was slow. The time course of the response by *Glossina* Malpighian tubules to these steroids seems similar both to that of larval *Drosophila* salivary glands, exposed to ecdysterone¹⁰ and to the response of vertebrate transporting epithelia to the mineralocorticoid aldosterone¹¹. It was thought that the delayed response of the *Glossina* tubule preparation might similarly be due to the time required for the sequence of events (receptor interaction, transcription and translation) necessary for cells to respond to a steroid hormone. The delayed recovery might reflect activity of the proteins mediating the action of the steroid hormone continuing after the stimulating steroid was removed. To verify this, Malpighian tubules were stimulated to secrete by ecdysone in the presence of $10 \mu\text{g ml}^{-1}$ actinomycin D which irreversibly inhibits transcription. Their response was not reduced (Table 1). If ecdysone stimulates secretion by *Glossina* Malpighian tubules by controlling protein synthesis it presumably therefore acts post-transcriptionally.

Another way in which steroids might increase the rate of secretion is by altering the permeability of the basal membrane of the tubule cells. The rate of secretion of *Glossina* Malpighian tubules is thought to be determined by the permeability of their basal membrane to sodium¹² and it has been suggested that ecdysteroids are able to alter the permeability of cell and nuclear membranes to sodium and potassium¹³. Cholesterol is also known to alter the permeability of cell membranes¹⁴.

The results of these experiments suggest new lines of investigation into both the control of insect Malpighian

Table 1 Rate of secretion of isolated Malpighian tubules in the presence of steroids

Steroid present	Mean rate of secretion (nl min ⁻¹)	2 × s.e.	n
None	0.3	0.09	12
Ecdysone	4.2	0.98	20
Ecdysterone	3.4	1.06	9
Cortisol	3.1	1.16	7
Cholesterol	3.3	1.88	6
Aldosterone	4.5	1.13	9
Ecdysone + $10 \mu\text{g ml}^{-1}$ actinomycin D	5.1	1.22	10

Steroids were used at a concentration of 10^{-6} M, except for cholesterol which is only slightly soluble in water. A saturated solution of cholesterol in Ringer (containing approximately 0.2 mg per 100 ml H₂O) was centrifuged before it was added to the isolated preparation. The concentration of cholesterol in solution was approximately 5.17×10^{-6} M.

tubules and the function of ecdysteroids in insects. It has subsequently been shown that in *Locusta* also ecdysterone and cholesterol stimulate secretion by *in vitro* preparations of the Malpighian tubules (A. Bernstein and W. Mordue, in preparation). *Glossina* tubules respond to ecdysteroids at concentrations within the physiological range and this response suggests a function for the high concentrations of ecdysteroids present in adult male insects. The action of ecdysteroids (which control the growth and development of the larval stages of the insect) on the process of excretion in the adult insect is especially interesting since the Malpighian tubules are one of the few organs which remain intact throughout metamorphosis. We have little knowledge of the identities or titres of steroids circulating in the haemolymph of adult insects. But, as this investigation suggests that they may have regulatory functions in insects, over and above that of controlling the development of the larval and pupal stages, this may become an interesting new field of study.

We thank Dr J. D. O'Connor and Professor A. E. Kellie for advice about preparation of anti-sera for the radioimmunoassay of ecdysteroids. J. K. thanks the British Council for a grant to visit Britain and J. D. G. and D. L. W. thank the Ministry of Overseas Development for support.

Meiotic crossing-over in lily and mouse

CYTOLOGICAL descriptions of meiosis have long been a staple of biology textbooks, but a biochemical account of the process with a comparable claim to universality has been unavailable. We present here evidence for a common pattern of DNA metabolism in male meiotic cells of lilies and rodents during the zygotene-pachytene stages when crossing-over is presumed to occur. The prevalence of a common pattern between species that are as phylogenetically distant as lily and mouse has led us to conclude that the organisation for meiotic crossing-over in at least higher eukaryotes is probably universal in distribution. Four components of the pattern have been identified in separate studies of lilies, mice and rats, most of which have been or are being published elsewhere¹⁻³: the transient appearance of a protein ('R-protein') that facilitates DNA reannealing; the programmed introduction of single strand nicks on completion or near completion of chromosome pairing; the repair of endogenously formed nicks and gaps either immediately following or overlapping the interval of nicking; the preferential localisation of gaps and nicks in specific DNA sequences.

We described previously a protein in nuclei of *Lilium* meiocytes but not of its somatic cells which, like the gene-32 protein, facilitated DNA reannealing⁴. A preliminary report on the presence of a similar protein in testicular nuclei of various mammals was also published⁵. This protein was judged to be significant to chromosome pairing and crossing-over because of its absence during premeiotic chromosome replication, its prominence during zygotene and pachytene, and the reduction of pairing and chiasma formation on disrupting its normal association with nuclear lipoprotein by colchicine treatment⁶. A more detailed study⁷ of the R-protein purified from rat testicular nuclei showed it to have properties distinctly different from those of unwinding proteins in calf thymus which have been thoroughly analysed by Herrick and Alberts⁸. The R-proteins from rat and lily, on the other hand, are very similar to the T4 gene-32 protein with respect to promotion of DNA reassociation and of duplex unwinding in Mg^{2+} -free medium. They are distinctive, however, in that the capacity for reassociation and DNA binding can be destroyed by phosphorylation with a cyclic AMP-dependent protein kinase. Dephosphorylation with alkaline phosphatase restores the binding capacity⁷, but, as we have since observed, not the capacity for reassociation.

We fractionated mouse spermatocytes according to spermatogenic stage and analysed each of the fractions for R-protein activity. Although the different meiotic stages of spermatocytes cannot be separated as well as those of *Lilium* microsporocytes, the respective profiles of R-protein activity during meiosis are very similar (Fig. 1). In both organisms, the R-protein is most prominent during the intervals of zygotene and pachytene when pairing and crossing-over occur. In neither organism is there any evidence for a substantial presence during premeiotic DNA replication when DNA synthesis is at least 300 times greater than during meiotic prophase. Circumstantial evidence thus indicates that in the case of the R-protein, unlike the gene-32 or similar microbial proteins, the recombinational function has been separated from the replicative one. Although the precise role of the R-protein in meiosis remains to be defined and its apparently marginal presence in somatic tissues needs to be explored, the evidence now available points to the conclusion that the R-protein is essential to chromosome pairing and/or crossing-over among higher eukaryotic organisms.

In *Lilium*, single strand nicks and gaps appear in nuclear

Fig. 1 Changes in R-protein during meiosis in lily microsporocytes (●) and rat spermatocytes (○). The data on lily are from previous studies⁴. To permit a rough comparison in R-protein content between the two organisms, we have recalculated the values on lilies so that the numbers for lily and mouse reflect approximately equal amounts of meiocyte DNA. Spermatocytes were separated by a modified Staput procedure⁹ into fractions designated by the predominant cell type: round spermatid (R-tid), early prophase (EP), late prophase (LP), and late spermatid (L-tid). Although R-tids are postmeiotic, the fraction is the only one containing cells in premeiotic S-phase and very early prophase. Separation of meiotic stages in the lily is unambiguous: Premeiotic interphase including S-phase (int.), leptotene (lept.), zygotene (zyg.), pachytene (pachyt.), Divisions I and II (I-II), telophase (tel.). Nuclei from pooled spermatocytes were suspended in a buffered medium consisting of 20mM Tris-HCl, pH 7.5-25mM KCl-3mM $CaCl_2$ -0.1mM dithiothreitol, sonicated for 45 s at 0°C, and the chromatin-free lipoprotein fraction isolated^{4,11}. The lipoprotein material was resuspended in buffered medium and assayed for duplex and single-stranded DNA binding activity¹¹. A discontinuous sucrose gradient was used to recover the bound DNA. The difference between the amounts of single strand and duplex DNA bound was considered to be R-protein. The activities are expressed in terms of R-protein content, based on assays of a purified protein which bound approximately 0.09 μ g (³H)T7-DNA per μ g R-protein.

DNA at about the time that the pairing of homologous chromosomes is completed⁹. We have interpreted such endogenously regulated nicking as a necessary condition for crossing-over and have adduced evidence for the absence of nicking in situations where crossing-over fails to occur. A pattern of DNA nicking similar to the one in lilies has now been found in mouse spermatocytes³. In both species, zonal sedimentation profiles of single stranded DNA are bimodal at pachytene and unimodal at all other stages of meiosis, thus reflecting the introduction of nicks at the pachytene stage. The unimodal profiles peak at about 105S in the lily and 160S in the mouse, corresponding to molecular weights of 1.8 and 5.1×10^8 (ref. 10). Significantly perhaps, the slower sedimenting component in each of the bimodal profiles peaks at about 62S corresponding to a molecular weight of 48×10^6 . The changes in proportion of 62S DNA at different stages of meiosis in lily and mouse are shown in Fig. 2. Although the fraction of 62S DNA at pachytene is slightly greater in the mouse, the total number of nicks per meiocyte is much larger in lilies, which have a haploid DNA content about 20 times that of mice. Since there are approximately 36 chiasmata per lily microsporocyte and 20 per mouse spermatocyte, the efficiency of converting nicks into crossovers is greater in mouse than in lily. There may indeed be an inverse relationship between genome size and efficiency of such conversion. In lily, there are about 1×10^4 nicks per crossover; in yeast, where a pattern of nicking similar to the one in lily has been

observed, 50% of the nicks seem to be converted into reciprocal crossovers¹¹. Although we have no information on the mechanism relating nicking to the ultimate event of crossing-over, the occurrence of meiotic nicking in yeast lily and mouse, is compelling evidence for the universality of endogenously regulated nicking in eukaryotes as a background condition for crossing-over.

Implicit in the profiles shown in Fig. 2 is the occurrence of sufficient repair synthesis during pachytene to restore the linear integrity of the DNA to its prepachytene level. Direct evidence for repair replication has been obtained in both mouse and lily by pulse labelling of pachytene cells that had previously incorporated bromodeoxyuridine during the premeiotic S-phase^{3,12}. But, meiotic cells, like somatic ones, can repair DNA lesions at almost any stage of development, so that nicking, whether endogenous or exogenous in origin, would be expected to promote repair synthesis. That endogenous pachytene repair synthesis shares many features with exogenously induced repair has been adequately documented. There are, nevertheless, two distinguishing features of the endogenous process. One of these is the elevated capacity for repair in pachytene cells, a property that has been well demonstrated in the mouse¹², and can also be demonstrated in lily. The other, more significant feature, concerns specific sites of nicking and repair, as discussed below.

Commonly, frequency of crossing-over between two loci in a chromosome is considered to be a function of the physical distance between them. Although broad exceptions to this relationship have been documented¹³, it might, nevertheless, be supposed that endogenous meiotic repair synthesis would be randomly distributed in the genome. This, however, is not the case. C_0t profiles of DNA synthesised during pachytene show that the endogenous synthesis occurs preferentially in moderately repeated sequences (Fig. 3). Such preference is a unique characteristic of meiotic repair and not of repair in general; radiation-induced repair tracks the C_0t profile of total DNA regardless of meiotic stage. In lily, 50%–70% of endogenous pachytene repair occurs in sequences that are repeated about 1–2,000 times per genome and constitute at least 0.1% of

Fig. 2 Changes in sedimentation behaviour of single-stranded DNA prepared from microsporocytes and spermatocytes at different stages of meiosis. The profiles are constructed from data obtained in analyses of gently lysed preparations over alkaline glycerol gradients. The proportion of 62S DNA is calculated from the weight distribution of DNA in the region of the gradient containing the 62S component. Designation of meiotic stages is the same as in Fig. 1. Stages beyond pachytene have been grouped under post-pachytene (Post-pachy.). Assignment of sedimentation characteristics to specific spermatocyte stages is easier than in the case of the R-protein because the 62S component is prominent only during the pachytene stage. ●, Lily; ○, mouse.

Fig. 3 Reassociation characteristics of mouse and lily DNA synthesised during the pachytene stage. The data displayed are from earlier analyses of *Lilium* microsporocytes¹⁸ and from recent analyses of mouse spermatocytes⁷. In the case of the mouse, the data on pachytene are from mice treated with hydroxyurea to inhibit semiconservative synthesis. In the absence of hydroxyurea, the pachytene profile, though essentially the same, is less pronounced because of contamination by S-phase cells⁶. C_0t characteristics of S-phase labelled DNA are included for comparison. ●, Lily; ○, mouse; ×, *Escherichia coli*.

the total DNA¹⁴. The precise lengths of the repeats have not been determined, but we estimate them to be in the neighbourhood of 100–200 bases¹⁵. In mouse, 50% of the repair occurs in sequences that are repeated about 400 times per genome; the proportion of DNA thus involved is undetermined but it cannot be detected by absorbance measurements, and is probably less than 1–2%. There is, however, one feature of pachytene synthesis in mouse spermatocytes which is not evident in lilies. In the profile shown in Fig. 3, about 25% of the pachytene label reassociates at a C_0t value below 10^{-2} . This rapidly reannealing region is being analysed in greater detail, but it is already clear that with 400–500 nucleotide fragments about 15% of the total pachytene label reassociates as foldback DNA, and that 1/3 of the label present in the foldbacks is in duplex form. This observation is pertinent to speculations about the involvement of hairpin loops in crossing-over^{16,17}. The location of repeated sequences in lily and mouse in relation to single-copy ones needs to be determined, but it is evident from Fig. 3 that pachytene labelling does not occur exclusively in repeat sequences but is also present among the lower repeat sequences.

The evidence, limited though it is, points unambiguously to the conclusion that in organisms as diverse as lily and mouse, metabolic events that are temporally associated with meiotic crossing-over share a common pattern. The preferential and programmed nicking of DNA in regions of moderate repeats, the similarity in spacing between nicked sites, and the temporal correlation between endogenous repair synthesis and cytological stage, are impressive examples of a conserved biochemical program for meiosis. In our opinion, these examples provide for the observed regularity in crossing-over among higher organisms.

Evidence for two active X chromosomes in germ cells of female before meiotic entry

THERE is considerable evidence that, as a result of some early embryonic event, the genes of one X chromosome in each somatic cell of the human female are not expressed¹. Studies of somatic tissues and cultured cells (including fibroblast clones) from human embryos, heterozygous for the common electrophoretic variant of glucose-6-phosphate dehydrogenase (G6PD), indicate that a single active X is present in cells from various tissues, at least by 5 weeks from conception². On the other hand, the presence of the heteropolymorphic form of the enzyme in oocytes of the heterozygous adult female³ and a 16-week-old foetus⁴ is compelling evidence that, in meiotic stage germ cells, there are two active X chromosomes; however, the basis for the two active chromosomes in oocytes is not clear. It is conceivable that germ cell progenitors escape inactivation because inactivation occurs when cells destined to become germ cells have already been imprinted. Alternatively, only a single X chromosome may be active in all cells of the early zygote, with the second X activated only in germ cells at some time after their differentiation. The third possibility, that germ cells are subject to inactivation, but that reactivation occurs when meiosis commences, has been suggested by Gartler *et al.* because they did not observe the heteropolymer in ovaries from a 12-week-old human foetus heterozygous for the G6PD variant^{5,6}. The ovary at that developmental stage contains approximately 23% germ cells, with a preponderance of premeiotic and leptotene germ cells⁷. But the implication that two functional X chromosomes are required for the onset of mammalian meiosis is not supported by evidence that XO mice produce normal gametes⁸. Using human foetal material, we have now obtained evidence against the third possibility.

We have studied ovarian extracts from foetuses heterozygous for the G6PD_A variant. Specimens were obtained

(according to an approved protocol and with maternal consent) from dead foetuses in the Fertility Control Unit of the Johns Hopkins Hospital, where every effort is made to assure the accuracy of historical data. Electrophoresis for G6PD was carried out on cellulose acetate gels as before². During this study, we obtained G6PD isozyme patterns from 35 males and 49 females of foetal age 14-21 weeks. The patterns observed in lung tissue from these specimens indicate that the frequencies of the G6PD_A and G6PD_B alleles in the foetus are essentially that observed in somatic cells of a comparable adult population, and that, as expected, males have a single isozyme (Table 1). The age of each specimen was estimated from time of conception, on the basis of last menstrual period and measurements of mean foot length⁹ and crown-rump length of the foetus (Table 2). From specimens obtained after urea-prostaglandin infusion, we ascertained 17 females of 14-21 weeks gestation who were heterozygous for the G6PD variants, and obtained ovarian tissue from 10 of them. From examination of more than 100 specimens obtained from suction procedures, we obtained a single appropriate specimen of ovary from a foetus of 8 weeks'

Table 1 G6PD phenotype of foetal lung specimens

* 23 further male specimens were ascertained, but not analysed for G6PD.

conceptual age. Foetal specimens were assayed directly for the G6PD phenotype and, in each case, samples of lung were used as the somatic cell control for the ovarian specimen. Ovarian extracts were enriched for germ cells by pressing the foetal ovaries gently under a cover glass^{5,10}.

The results of electrophoretic studies of these 11 specimens are presented in Table 2 and Fig. 1. In each case, lung specimens revealed the heterozygosity, having both A and B isozymes. In all ovarian specimens studied, there were three isozymes with the heteropolymer migrating between the A and B bands. The intensity of the heteropolymer varied considerably. The band ratio of 1A:2 heteropolymer:1B, which might be expected for the three enzymes in a pure population of oocytes, was not seen even in the specimens from the most mature foetuses (20-21 weeks), indicating dilution of the ovarian specimen by non-germ cells. We confirmed previous observations that the heteropolymer was less intense in cells of younger

specimens', most likely because of relatively greater contamination of these specimens by ovarian somatic cells. This is consistent with the lesser number of germ cells known to be in ovaries of younger fetuses^{7,11}. In contrast to previous observations³, we observed a heteropolymer even in the specimen from the 8-week-old foetus (Figs 1f and g and 2), at a time when the germ cell population is essentially premeiotic^{7,11}. Although a few germ cells in the leptotene and zygotene stages of first meiotic metaphase have been described in the 12-13-week ovary, meiotic cells are not found in significant numbers until 16 weeks from conception¹². The ovary of the 8-week specimen was at the lower limit of size necessary for the identification of the pertinent tissue; therefore, it is unlikely that studies of isozyme analysis of ovaries in younger foetal specimens are feasible.

Our observations indicate that two X chromosomes are functioning in female germ cells, even before meiotic entry, and they are supported by the cytological observations of Ohno, who did not observe a precociously condensed X chromosome in mouse oogonia, nor in cells entering meiosis¹². Because there seemed to be one condensed X chromosome in primordial germ cells of the yolk sac, he suggested that germ cells are X-inactivated but reactivated at the time of differentiation of primordial

germ cells into oogonia in the ovary. The presence of two active X chromosomes in premeiotic germ cells, reported here, does not differentiate between escape from inactivation and reactivation (or activation of the second X), but excludes reactivation coincident with the onset of meiosis.

Transcriptional controls and dosage compensation in *Drosophila melanogaster*

DOSAGE compensation is the equalisation of X-linked gene products in males and females. In *Drosophila* there is substantial evidence to support the contention that both X chromosomes are simultaneously active in somatic cells of females¹, and that the regulatory mechanism operates at the level of transcription^{2,3}. Most discussions of this mechanism have focused on the modulation of regulatory factors controlling the rate of RNA synthesis per template^{4,5}. A change in the level of transcription may also be achieved by altering the quantity of template. We present here various arguments and some experimental evidence discounting controlled variation of total template as the basis for dosage compensation in *Drosophila melanogaster*.

Three means by which the number of copies of X-linked genes may be equalised in male and female nuclei come to mind. First, the X chromosome may replicate earlier during the phase in males than in females. This is thought to be the case in polytenic nuclei of larval salivary glands^{6,7}. During a portion of the cell cycle, old and new copies of X-linked genes would be available

for transcription in male cells; the number of genes per cell would, therefore, be the same in males and females until that time when replication of X-linked genes occurred in the latter. A serious objection to this model is based on the observation that the S phase constitutes at most 30%–40% of the cell cycle (measurements performed on cleaving embryos and cells in culture)^{8–10}. The male cells, therefore, spend a large portion of their existence in G1 or G2 where the dosage of their X-linked genes relative to that of autosomal genes is either 1:2 or 2:4. Furthermore, if the difference in time of X chromosome replication between males and females were significant, a considerable proportion of the cells sampled at any given time in males and in females should have equivalent X DNA content. But, microspectrophotometric measurements of Feulgen-stained chromosomes indicate that the paired X's in the salivary gland nuclei of female larvae have twice the DNA content of the single X in males (each measurement is made in reference to an autosomal, internal control)^{11–12}. It is, therefore, improbable that the early replication of X-linked genes in male cells could lead to equal transcriptional steady states in males and females.

A second possibility for template modulation would be the differential replication of X-linked genes in males. The unequal replication of specific sequences of the polytenic X chromosome in larval salivary glands is well documented. In a fully mature salivary gland chromosome, the centric heterochromatin including the highly repetitive DNA sequences has not undergone any endoreplication; the nucleolus organiser region containing the ribosomal RNA cistrons is present in 150 to 200 laterally redundant copies; the euchromatic portion of the chromosome is represented by more than 1,000 copies^{13,14}. If the coding segments of all structural genes were to undergo an extra round of replication in male cells, their dosage would become equal to that of female cells. Recent experimental evidence makes the differential replication model of dosage compensation unlikely. Electron microscope measurements of nascent RNA transcripts suggest that these molecules are of considerable size, perhaps corresponding to entire chromomeres which, in *Drosophila*, average 30 kilobases (kb) in length¹⁵. The median size of poly(A)-containing nuclear RNA is 6 kb, representing 20% of an average chromomere¹⁶. In terms of the model, this should lead to a substantial amount of extra DNA in males which, as mentioned above, does not seem to be present.

Finally, the equalisation of effective X chromosome

coding sequences in males and females may be achieved through polyteny itself. If only a small fraction of all strands were active in transcription, males may compensate for X-linked gene dosage differences by transcribing twice the number of strands per X chromosome as would be active in females. Implicit to this model is the contention that when gene activity is measured in whole organisms at the level of enzyme activity or of a terminal phenotypic product (eye pigment, for example), the compensatory effect stems from gene activity in polytenic cells. This cell type is found in both larvae and adults and may be ubiquitous enough to mask the lack of compensation in the strictly diploid tissues of the organism.

To test whether dosage compensation is the result of some mechanism inherent to polytenisation, we have compared the expression of X-linked genes in imaginal disks and larval brain to that in larval fat body. The brain is mostly diploid with a very small fraction of cells which may be polytenic^{14,17}; imaginal disk cells are diploid¹⁷; fat body cells are clearly polytenic¹⁸. Table 1 shows activity levels of two X-linked enzymes (glucose-6-phosphate dehydrogenase—G6PD, and 6-phosphogluconate dehydrogenase—6PGD) normalised to the activity levels of three autosomal enzymes (NADP-dependent isocitrate dehydrogenase, α -glycerophosphate dehydrogenase, and aldehyde oxidase). Measurements were performed in larval tissues and adult thoraces and heads. All male individuals carried w^+Y , a Y chromosome bearing a small X fragment which includes the structural gene of 6PGD. Gene dosage for this enzyme is, therefore, the same in males and females, providing control evidence that activity differences of the magnitude expected could be detected by our experimental procedure. The male-female ratios of normalised G6PD activity are equal to or slightly greater than one, while the ratios of 6PGD activity are slightly less than or equal to two, in disks, fat body and adult tissues. These observations suggest the occurrence of dosage compensation in all these tissues.

In summary, three possible models for equalising the number of copies of X-linked genes in *Drosophila* males and females have been considered. Existing data regarding the amount of DNA in X chromosomes and the proportion of the S phase in the cell cycle have been used to discredit early replication of the male X as a possible explanation for dosage compensation. It is unlikely that differential endoreplication of X-linked structural genes is occurring in males. Finally, we have shown that compensation cannot be ascribed to polytenisation *per se*. Therefore, we conclude that mechanisms that vary the relative

Drosophila melanogaster stock, $y w^+/w^+Y$ (y , yellow; w^+ , white-apricot) was raised at 22°C on standard medium. Imaginal disks (with attached brain) and fat body were dissected from late third instar larvae in *Drosophila* Ringer's. Adult flies with abdomens removed were also used to prepare extracts. Imaginal disks from about 80 larvae, fat body from 15 female or 25 male larvae, or the anterior end of eight adults comprised a single sample. Tissues were transferred to a 1.5 ml Brinkman-Eppendorf microtest tube and homogenised in 0.125 ml of distilled water with a Teflon homogeniser. The homogenates were allowed to stand on ice for 20 min, centrifuged at 12,000g, and the supernatant was used as the extract for enzyme assays. Assay conditions for G6PD, 6PGD, α -GPDH and IDH were as described previously¹⁹. AO assay conditions were those of Dickinson²⁰. Normalised activity measurements were obtained by dividing X-linked gene activity by autosomal gene activity for each extract. The mean ratio is given \pm s.e. with the number of extracts in parentheses. The male/female values are ratios of the means.

amounts of template in males versus females are not adequate to account for dosage compensation in *Drosophila*.

Endocytosis of red blood cells or haemoglobin by activated macrophages inhibits their tumoricidal effect

MICE with chronic *Bacillus Calmette-Guérin* (BCG) or *Toxoplasma gondii* infection have increased resistance to tumour growth, and peritoneal macrophages from these mice can selectively kill neoplastic cells *in vitro* by non-phagocytic means^{1,2}. Although the actual molecular mechanism of killing is unknown, the tumoricidal macrophage (TM) vacuolar system is probably involved. Phase contrast³ and electron microscopy studies⁴ have suggested the translocation of TM lysosomes into tumour cells with subsequent tumour cell death. Trypan blue, an inhibitor of lysosomal enzymes, or hydrocortisone, a membrane stabiliser and inhibitor of membrane fusion, will suppress the *in vitro* tumour cell killing by TM (ref. 3). We report here that endocytosis of red blood cells (RBC), haemoglobin or haemoglobin degradation products by TM inhibits their tumoricidal effect.

In vitro macrophage-mediated tumour cell killing was assayed as described previously³ with some modifications as described in the legend to Fig. 1. Tumour cell killing was assessed by microscopic examination or by measurement of tritiated thymidine (³HTdR) release from pre-labelled 3T12 cells⁵. The results were comparable using TM from either BCG- or *T. gondii*-infected mice.

Results of a typical experiment are shown in Fig. 1. Control TM destroyed very nearly all the 3T12 cells (Fig. 1a). But if the TM had phagocytosed RBC, the killing was markedly suppressed. In Fig. 1b, with an RBC:TM ratio of 4:1, there is complete inhibition of the killing. The inhibition seems to be proportional to the RBC:TM ratio with less complete suppression of killing apparent in Fig. 1c and d with RBC:TM ratios of 2:1 and 1:1, respectively. Experiments using a ³HTdR release assay for tumour killing gave comparable results. For example, the ³HTdR release expressed as a percentage of maximal release (100% release with no RBC added) was 3.2 ± 2.0%, 9.5 ± 3.4%, and 14.4 ± 2.7% for RBC:TM ratios of 3.00:1, 1.50:1, and 0.75:1 respectively. Figure 2 shows the microscopic features of the inhibitory effects of RBC.

Inhibition was seen when RBC were phagocytosed by the TM. Heat-damaged, glutaraldehyde-treated⁷, or antibody-opsonised⁸ (Cordis Laboratories, rabbit IgG anti-sheep RBC) RBC were all

avidly phagocytosed (>90% of the TM contained ≥2 RBC at an RBC:TM ratio of 4:1). If fresh bovine RBC and serum, or fresh mouse RBC and serum syngeneic to the TM (C₃H-He) were present throughout the assay, no TM phagocytosis of RBC occurred. In these situations, there was no inhibition of tumour killing despite close contact between RBC and TM. Of the species examined (human, bovine, rabbit, mouse, chicken, sheep), none was tested that did not suppress killing as long as the RBC were phagocytosed. Syngeneic RBC inhibited if they were phagocytosed. The TM remained viable after the phagocytosis as judged by Trypan blue exclusion, absence of release of the cytoplasmic enzyme lactic dehydrogenase (LDH) (refs 9, 10) and maintenance of their adherence to plastic. TM that had phagocytosed RBC in pre-incubation (with free RBC then washed away, also had diminished tumoricidal effect. *In vivo* loading of TM by intraperitoneal injection of glutaraldehyde-treated RBC 3 d before the assay also resulted in TM with suppressed tumour killing ability.

Fig. 1 Photograph of giemsa-stained assay of macrophage-mediated tumour cell killing demonstrating inhibition by red blood cells (RBC). Swiss Webster female mice were infected with either the Paris strain of BCG intraperitoneally (i.p.)³, or the C56 strain of *Toxoplasma gondii* i.p.⁶. At 2–3 weeks after BCG infection or 8–24 weeks after toxoplasma infection, the mice were injected with 2 ml of sterile 10% peptone i.p., and 3 d later the peritoneal cells were collected. Peritoneal cells (4×10^5) in 0.1 ml of Dulbecco's modification of Eagle medium supplemented with streptomycin ($100 \mu\text{g ml}^{-1}$), penicillin (100U ml^{-1}), HEPES buffer (0.02 M), and glucose (1 mg ml^{-1}) (DMM) were placed into the microtitre wells (Falcon plate 3040) and incubated for 60 min at 37°C in humidified 95% air–5% CO_2 . The nonadherent cells were removed then by washing twice with 0.15 M NaCl (saline). Human RBC were obtained from heparin-anticoagulated blood and washed three times with saline. The RBC were fixed for 30 min at room temperature in 1% glutaraldehyde–saline and washed five times with 15–20 volumes of saline each time. After removal of nonadherent peritoneal cells, 3T12 tumour cells (6×10^3 per well) and appropriate RBC additions were applied in DMEM with 10% foetal calf serum. The plates were incubated for 60 h at 37°C in humidified 95% air–5% CO_2 , fixed, and stained with giemsa. Multilayers of 3T12 cells stain dark while TM are not grossly stained. The defects in the tumour cell multilayer apparent in the '3T12' column on rows a and d are artefacts due to detachment and rolling up of the multilayer from the substrate. Row a, (control, no RBC added) reveals the tumoricidal effect of the macrophages seen in the 'TM + 3T12' wells when compared to the control '3T12' well which has no TM. Numbers of RBC in test wells are: b, 1×10^6 ; c, 5×10^5 ; d, 2.5×10^5 . b–d Demonstrate the RBC inhibition of TM-mediated 3T12 killing with grossly visible multilayers of 3T12 in the 'TM + 3T12' wells. Microscopic examination of a '3T12' well stained 3 h after seeding 6×10^3 3T12 (not shown) reveals 33–37 cells per 300 power field. The 'TM + 3T12' wells in (a) have 0–3 3T12 cells per 300 power field. But, in (d), killing is less complete with many fields having more than three tumour cells and several having a multilayer. Virtually all fields in b and c have multilayers of 3T12 cells.

The act of phagocytosis, *per se*, along with all the accompanying metabolic consequences¹¹, seemed not to be responsible for the RBC-induced inhibition of tumour killing. Latex spheres, either 5.7- μm diameter styrene divinyl benzene (SDB) or 1.01- μm diameter polystyrene (Dow Chemical), were avidly endocytosed by the TM. There was, however, no inhibition of tumoricidal activity until the sphere:TM ratio exceeded 1000:1 for the polystyrene spheres or 100:1 for the SDB spheres. At these ratios, the TM were clearly dead as evidenced by Trypan blue uptake and LDH release. For example, at an SDB:TM ratio of 3:1, there was no inhibition of 3T12 killing and 0% extracellular release of TM LDH, whereas there was complete inhibition of 3T12 killing at an SDB:TM ratio of 100:1 with 61.4% release of the total TM LDH.

Red blood cell ghosts that were phagocytosed after glutaraldehyde treatment or antibody opsonisation did not inhibit killing even at a ghost:TM ratio of 100:1. But, endocytosed¹² ghost-free RBC lysate or chromatographically separated haemoglobin (Hb) was inhibitory at Hb levels $\geq 250 \mu\text{g ml}^{-1}$ (either native or heat denatured). Haem-free globin, prepared by acid-acetone extraction of Hb (ref. 13), was quite unstable in culture media at 37 °C and precipitated as 0.5–1.0- μm diameter spherules. These very hydrophobic globin particles were endocytosed by TM and inhibited tumour killing at levels of 500–1000 $\mu\text{g ml}^{-1}$. Methaemalbumin prepared as described by Tenhunen *et al.*¹⁴ was inhibitory at levels of 500–2,000 $\mu\text{g ml}^{-1}$, whereas albumin treated comparably but lacking haem had no effect on tumour killing. To determine whether the iron of the haem was responsible for the inhibition, ferric chloride (FeCl_3), ferrous sulphate (FeSO_4), and iron dextran (Imferon) were examined. Imferon (200–1,000 μg elemental iron per ml) or FeCl_3 or FeSO_4 (1–40 $\mu\text{g ml}^{-1}$), when left in through the killing assay or used in a pretreatment fashion for 3 h in serum-containing media, completely inhibited the killing by TM. Dextran (average molecular weight 40,000) had no suppressive effect. Non-haemoglobin erythrocyte proteins did not inhibit killing. As much as 1,000 $\mu\text{g ml}^{-1}$ endotoxin-free superoxide dismutase (SOD, Truett Laboratories), catalase (Boehringer), or bovine serum albumin (Pentex)¹⁵ did not suppress macrophage-mediated tumour cell killing. Enhancement of endocytosis of SOD, catalase, or albumin by heat denaturation (120 °C for 20 min followed by sonication if necessary to disperse the denatured proteins) likewise had no effect. Native or heat denatured myoglobin did not inhibit. Table 1 summarises the suppressive effects of various additives.

These results suggest that RBC, Hb, globin, and iron inhibit the tumoricidal effect of activated macrophages. Because damaged

Table 1 Effects of various additions on macrophage-mediated tumour cell killing

Addition	Tumoricidal effect
None	4+
RBC (phagocytosed)*	0
RBC (not phagocytosed)*	4+
RBC ghosts† (phagocytosed)*	4+
RBC lysate‡	0
Haemoglobin‡§	0
Myoglobin‡	4+
Methaemalbumin	0
Albumin‡	4+
Globin‡	0
FeSO_4 or FeCl_3	0
Iron dextran (Imferon)‡	0
Catalase‡	4+
Superoxide dismutase‡	4+

Additions were tested throughout the 60 h *in vitro* assay or in a 2 h pretreatment of TM before tumour cell challenge. All were negative for endotoxin as judged by the limulus amoebocyte lysate test¹⁶. The tumoricidal effect was judged from microscopic assay of microtitre plates stained after 60 h culture³. 4+ Tumoricidal effect signifies 0.33T12 cell per 300 power field among the TM; zero tumoricidal effect signifies a multilayer of 3T12 cell per 300 power field among the TM.

*RBC TM ratio of 4:1.

||20 $\mu\text{g ml}^{-1}$.

RBC, Hb, globin, or iron rapidly accumulated in macrophage secondary lysosomes, we interpret our findings as further evidence for involvement of the TM vacuolar system in the non-phagocytic tumour killing process. Vacuolar system and/or plasma membrane damage by iron-induced lipid peroxidation¹⁹, reaction with -SH groups²⁰, or interference with Ca^{2+} transport²¹ may account for the suppressed activated macrophage tumoricidal capability. The lack of inhibition by myoglobin and catalase (which also contain haem moieties with iron) may relate to substrate specificity of haem oxygenase with less or more gradual liberation of 'free' iron from these proteins in the macrophage vacuolar system. Haem oxygenase has little or no degradation effect on myoglobin²². The inhibitory effect of globin is not fully understood, but may relate to its hydrophobic nature. Further elucidation of the mechanisms of the inhibitory effects of RBC, Hb, and Hb degradation products may lead to a more basic knowledge of macrophage-mediated tumour killing. In addition, these observations may aid in understanding the pathogenesis of tumour development in certain clinical situations in man.

There is evidence that iron may contribute to tumour growth in certain experimental and clinical conditions (the occurrence of sarcomas at sites of repeated parenteral iron injections in animals²³ and man²⁴; the increased incidence of hepatomas and other epithelial malignancies in idiopathic haemochromatosis²⁵, acute myeloblastic leukaemia in idiopathic refractory sideroblastic anaemia²⁶, lung carcinoma in mice inhaling iron oxide dust²⁷, and lung carcinoma in haematite miners²⁸). The mechanism by which iron promotes growth of tumours *in vivo* is complex and poorly understood. Some have proposed that iron may act as a primary carcinogen by inducing mutations in somatic cells²⁹, while others have noted a potentiating or cocarcinogenic effect of ferric oxide on chemical carcinogen-induced lung tumours in hamsters³⁰. In addition, some have noted stimulation of tumour cell growth *in vitro* by FeCl_3 (ref 31). Our observed inhibition of the tumoricidal effect of activated macrophages by RBC, haemoglobin, or iron cannot be accounted for by direct effects on tumour cells by the additives, since the inhibition was observed if macrophages had endocytosed the RBC, Hb, or iron before addition of the tumour target cells to the cultures (see Table 1). Therefore, based on the results reported here, we believe that iron could operate through an additional mechanism (inhibition of macrophage tumour killing function) to decrease *in vivo* resistance to tumour development.

Activated macrophages may be the effector component of a

Fig. 2 Photomicrographs from giemsa-stained 'TM+3T12' wells of cytotoxicity assay demonstrating RBC inhibition of macrophage-mediated tumour cell killing. Pictures were made at 60 h from a single experiment as described in Fig. 1 legend. *a*, The TM without added RBC have destroyed the majority of the 3T12 cells. This typical field shows one residual tumour cell among the TM. *b*, The TM with phagocytosed RBC did not kill the 3T12 cells. This typical field shows numerous 3T12 cells with their prominent nucleoli among the RBC-laden TM ($\times 200$).

surveillance system for the detection and destruction of newly emergent clones of neoplastic cells^{3,2}. Pathologic conditions which produce large amounts of RBC, Hb, or Hb degradation products within the macrophage vacuolar system could suppress tumour cell killing and effectively paralyse this surveillance system.

Inhibition of adipose conversion of 3T3 fibroblasts by tumour promoters

TUMOUR-PROMOTING compounds are not themselves carcinogenic, but can induce skin tumours in mice pre-treated with a subcarcinogenic dose of a chemical carcinogen^{1–3}. They have been shown to produce many different biochemical and biological effects on cells^{3,4}, but the mechanism of promotion is not known. Two recent reports describe the effects of the phorbol diester series of tumour promoters on cell differentiation *in vitro*. Cohen *et al.*⁵ observed that 12-O-tetradecanoyl-phorbol-13-acetate (TPA; phorbol myristate acetate), a potent promoter, inhibits myogenesis in chick embryo muscle cultures. We have reported^{6,7} that TPA and other tumour-promoting phorbol diesters inhibit spontaneous and induced differentiation of Friend erythroleukaemia cells in culture. We now describe another cell system, mouse preadipose cells, in which tumour promoters inhibit terminal differentiation, and confirm in these cells our original observation⁶ that there is a good correlation between the ability of a particular phorbol diester to promote tumours in mouse skin and its ability to inhibit terminal differentiation of cells in culture.

A clone of BALB/c 3T3 fibroblasts⁸ was obtained from Dr R. Tennant, Oak Ridge National Laboratory. In our laboratory, cells of this clone (designated clone A31T) behave as preadipose cells and differentiate to mature adipocytes in a manner similar to that already seen in some clones of Swiss 3T3 fibroblasts^{9–12}. When cultures are

Fig. 1 Effect of TPA on adipose conversion of clone A31T fibroblasts. Cells were seeded into gridded 60-mm plastic Petri dishes at a density of 4×10^4 cells per cm^2 . After 3–4 d, when the monolayers were confluent, and again on day 4, the cultures were refurnished (\uparrow) with fresh medium containing insulin $0.1 \mu\text{g ml}^{-1}$ and TPA. The number of lipid-positive cells per 4 mm^2 was scored by microscopic observation without staining every 2–3 d and confirmed after staining with oil red O at the termination of the experiment. ●, Control; △, TPA $1.6 \times 10^{-7} \text{ M}$; □, TPA $1.6 \times 10^{-8} \text{ M}$.

held as confluent monolayers, the cells begin to accumulate lipids. They soon become mature adipocytes in which the cytoplasm is filled with lipid droplets and lose the ability to divide; after a few weeks, more than half the cells in the monolayer may be mature adipocytes. Both immature and mature adipose cells are easily identified either without staining or after staining with the lipid-specific stain oil red O. Stock cultures of clone A31T were grown in Eagle's basal medium supplemented with 10% foetal calf serum and were subcultured at 1:10 ratios just as the monolayers reached confluence, so that adipose conversion was kept at a minimum.

TPA and 4 α -phorbol-12,13-didecanoate (4 α -PDD) were purchased from Consolidated Midland; phorbol-12,13-didecanoate (PDD), phorbol-12,13-dibenzoate (PDB) and phorbol-12,13-diacetate (PDA) were the gift of Dr R. K. Boutwell, University of Wisconsin. Stock solutions ($1.6 \times 10^{-4} \text{ M}$ in acetone) of the phorbol diesters were stored at -20°C and diluted in medium as required.

The effect of TPA on adipose conversion in clone A31T fibroblasts is shown in Fig. 1. In control cultures, the number of lipid-positive cells increased at the rate of approximately 15 cells per 4 mm^2 per d whereas in cultures treated with $1.6 \times 10^{-7} \text{ M}$ or $1.6 \times 10^{-8} \text{ M}$ TPA, there was no increase in the number of lipid-positive cells during with 7-d period of observation. With a 10-fold lower concentration of TPA, adipose conversion was inhibited for the first 4 d, but by 7 d the number of lipid-positive cells was similar to the number in control cultures.

The inhibitory effect of TPA was reversible after 7 d by refeeding the cultures with control medium. The number of lipid-positive cells increased thereafter at approximately the same rate as in control cultures never exposed to TPA.

The inhibitory effects of TPA on adipose conversion in clone A31T were similar whether or not insulin was in the medium, although insulin did enhance conversion^{11,12}. In one experiment, after 10 d the number of lipid-positive cells in control cultures with insulin $0.1 \mu\text{g ml}^{-1}$ was 82 per 4 mm^2 and without insulin, 58 per 4 mm^2 ; the numbers in TPA ($1.6 \times 10^{-7} \text{ M}$)-treated cultures were 2.1 and 2.8, respectively.

As has been reported with other 3T3 cell lines^{13,14}, TPA stimulated multiplication of clone A31T cells and increased the saturation density of the monolayers. Thus,

at the termination of the experiment shown in Fig. 1, cultures treated with 1.6×10^{-7} M TPA had 3.2×10^6 cells per plate, 0.15% of which were lipid positive, whereas control plates had 1.6×10^6 cells with 2.7% lipid positive.

The effects on adipose conversion of a series of phorbol diesters with a range of tumour-promoting activity in mouse skin^{2,15,16} are shown in Fig. 2. At the same concentration (1.6×10^{-7} M), the three promoters (TPA, PDD and PDB) completely inhibited adipose conversion whereas the three non-promoters (PDA, 4 α -PDD and phorbol) had no effect on conversion. The three active promoters also enhanced the saturation density of the cell monolayers approximately twofold; the three non-promoters had no effect on cell number.

The inhibitory effect of the promoters on adipose conversion was not permanent, even when the cultures were refurbished with fresh solutions of the phorbol diesters every 3–4 d. In five separate experiments, the inhibition of conversion by TPA (1.6×10^{-7} M) persisted for 14–18 d (Table 1), after which time the number of lipid-positive cells slowly increased. PDD and PDB, however, inhibited adipose conversion for only 7 d; after that time there was a rapid and sudden increase in adipose conversion. In the experiment shown in Table 1, for example, the number of lipid-positive cells per 4 mm² in PDD-treated cultures increased from 0 on day 7 to 184 on day 10. In PDB-treated cultures, there was an increase from 1.2 to 167 positive cells. These increases in adipose conversion first became evident on days 8 to 9 when there seemed to be an almost synchronous increase in the number of immature adipocytes; a few days later, these cells were fully mature adipocytes filled with lipid. Following this spontaneous release from the inhibitory effects of PDD and PDB, the percentage of lipid-positive cells gradually approached the percentage in control cultures (Table 1). Thus, on day 14 the absolute number of lipid-positive cells in PDD- and PDB-treated cultures was greater than in control cultures, but since the treated cultures had almost twice as many cells, the percentage of lipid-positive cells in the three groups was similar.

The finding that tumour-promoting phorbol diesters inhibit terminal differentiation in cultures of three different cell types, erythroleukaemia cells^{6,7}, muscle cells⁸ and preadipose cells, suggests that inhibition of terminal differentiation of cells in culture may be a general property of tumour promoters. They inhibit differentiation reversibly at concentrations that are not cytotoxic and that either stimulate or have no effect on cell division.

The phorbol diesters that inhibit adipose conversion of

Fig. 2 Effect of phorbol diesters on adipose conversion of clone A31T fibroblasts (Fig. 1 for procedure). The phorbol diesters were all tested at the same molar concentration, 1.6×10^{-7} M. ●, Control; △, TPA; ▲, PDD; X, 4 α -PDD; □, PDB; ○, PDA; ■, phorbol.

Table 1 Long-term effects of phorbol diesters on adipose conversion

Number of lipid-positive cells per 4 mm ²				
Day	Control	TPA	PDD	PDB
3	3.7 ± 3.0*	0	0	0
7	106 ± 15	0.5 ± 0.9	0	1.2 ± 2.4
10	169 ± 15	12 ± 2.3	184 ± 22	168 ± 22
14	223 ± 30	3.4 ± 1.2	368 ± 65	> 500
17	240 ± 52	6.1 ± 4.3	—	—

% lipid-positive cells				
Day	Control	TPA	PDD	PDB
3	0.1	0	0	0
7	2.7	< 0.1	0	< 0.1
10	4.8	0.1	3.0	2.0
14	6.3	< 0.1	6.0	6.8

Cultures of clone A31T fibroblasts were refurbished on days 0, 4, 7, 11 and 14 with medium containing the phorbol diesters at a final concentration of 1.6×10^{-7} M. On day 0, there were 2.1×10^6 cells per plate. By day 3, the cell monolayers had attained densities that remained essentially unchanged through day 14. The mean number of cells ($\times 10^{-6}$) per plate \pm s.d. from days 3–14 was: control, 2.0 ± 0.3 ; TPA, 3.9 ± 0.1 ; PDD, 3.3 ± 0.4 ; PDB, 4.0 ± 0.5 .

*Mean \pm s.d. of five squares.

clone A31T cells stimulate cell division the first time they are added to confluent cultures. The cells seem to retain their density-dependent growth controls during repeated refurbishing of the cultures with fresh solutions of phorbol diesters; the saturation densities remain essentially constant without cells being shed into the medium. This suggests that inhibition of differentiation in these cells may not be dependent on continuous cell cycling.

The reasons for the spontaneous release of clone A31T cells from the inhibitory effects of the promoters are not known. In contrast to these cells, Friend erythroleukaemia cells do not seem to become refractory to the inhibitory effects of the promoters on spontaneous differentiation; the extent of inhibition has remained the same in erythroleukaemia cells maintained for six months in the continuous presence of TPA⁷.

Tumour promoters induce many diverse effects on cells in culture⁴. It must be determined whether the inhibitory effects of promoters on differentiation are related to any of the other effects or to the mechanism of promotion itself. The ability of promoters to shift the cell population from a commitment to differentiate and become end cells to a commitment to maintain or increase the size of the stem cell pool, does suggest at least one possibility for the mechanism of promotion. The inhibition of terminal differentiation by tumour promoters may give cells in which the potential for malignancy has been initiated by a carcinogen, but is not yet expressed, additional time to convert to tumour cells before becoming end cells. Several investigators^{17,18} have proposed that tumour promoters act *in vivo* by interfering with normal cell differentiation. Our findings support those suggestions.

Effect of microtubular antagonists on lymphocyte mitogenesis

SEVERAL different classes of mitogens have been discovered¹. Stimulation of lymphocytes by all classes of mitogens results in cellular division, but it is not known whether all mitogens act on the cell membrane in identical fashion or result in triggering of the same cytoplasmic messenger. We have investigated the inhibitory effect of microtubule disrupting drugs on lymphocytes transformed by two methods. We report here that colchicine and vinblastine inhibit lectin-mediated mitogenesis at low concentrations, while cells stimulated by cell surface oxidation are inhibited only by much higher concentrations of these drugs. It seems that intact microtubules are necessary for lectin-mediated but not for cell surface oxidation-mediated mitogenesis.

Yahara and Edelman have demonstrated that microtubules and microfilaments exist in association with the lymphocyte cell surface². Edelman *et al.* have hypothesised that a colchicine-binding protein system may be a crucial link in the transmission of information from the cell membrane to the nucleus³. In support of this is the finding that drugs which disrupt microtubules block lectin-induced stimulation of lymphocytes at low drug concentrations^{4,5}.

We stimulated lymphocytes with two different classes of mitogens, (1) the plant lectins concanavalin A (con A) and phytohaemagglutinin (PHA) and (2) enzymatic oxidation of the cell surface by means of sequential additions of neuraminidase and galactose oxidase (NG) (ref. 6). Both classes of mitogens are known to selectively stimulate T cells⁷.

The effect of vinblastine on lymphocyte transformation measured by ³H-thymidine uptake is shown in Fig. 1. There is a significant difference between the amount of vinblastine needed to inhibit lectin-mediated stimulation and that amount needed to inhibit NG-treated lymphocytes ($P < 0.02$). Vinblastine had almost no inhibitory effect on NG-treated cells until a concentration of 10^{-5} M was reached. Lectin-treated cells were inhibited by drug concentrations 100 to 1,000-fold less.

The curve describing thymidine uptake as a function of antagonist concentration for NG-treated cells is suggestive of simple saturation kinetics, while the curves for lectin-stimulated cells show evidence of a more complex co-operative interaction. Colchicine gave results similar to those found with vinblastine (Fig. 2). Cytosine arabinoside, a drug known to directly interfere with DNA synthesis¹⁰, inhibits both groups to the same extent while showing similar inhibition kinetics (Fig. 3). This suggests that, not surprisingly, lectin- and NG-mediated stimulation share a common pathway at the level of DNA synthesis.

Table 1 illustrates the $-\log_{10} K_{50\%}$ of colchicine, vinblastine, and cytosine arabinoside for lymphocyte blastogenesis induced by lectins and cell surface oxidation. The significant difference between lectin- and NG-treated cells is evident for both vinblastine and colchicine although vinblastine proved to be a slightly more potent antagonist. Edelman *et al.* have hypothesised that a colchicine-binding

protein system has a role in the mediation of interactions between receptors on cellular membranes and the cytoplasm as well as in mitogenesis³. Microtubular inhibitors also inhibit mitogenesis in neuroblastoma and mouse 3T3 cells as well as in lymphocytes¹¹. Our results support reports^{4,5} that colchicine and vinblastine are effective inhibitors of lymphocyte mitogenesis and do not support the isolated report that vinblastine is not inhibitory¹².

Resch *et al.* have shown that three cellular events which occur in transformed lymphocytes before the initiation of DNA synthesis were not inhibited by colchicine or vinblastine¹³. They concluded that microtubules are not involved in the initiation of lymphocyte activation because the disruption of these cytoplasmic structures should also affect cellular events which occur before DNA synthesis. This conclusion is justified only if those early cellular events

Fig 1. Effect of vinblastine on lymphocyte transformation. Blood was obtained from human donors free of any acute or chronic illnesses and on no medications. Lymphocytes were isolated using the method of Boyum⁸. The cell population was made up of an average of 85% lymphocytes, 12% monocytes and 3% neutrophils. Cell viability following isolation and after treatment with NG or lectin was always over 95% as measured by Trypan blue exclusion and fluorescein diacetate uptake⁹. Cells were cultured in McCoy's 5A Medium (Microbiological Associates) supplemented with 10% autologous serum at a cell density of 1×10^6 cells per ml, in Nunc serum tubes (Vanguard International). The cultures were put in a humidified atmosphere of 5% CO₂, 95% air at 37 °C. At 48 h, 1 μ Ci ³H-thymidine (TdR), specific activity 6.7 mCi mmol⁻¹ (New England Nuclear) was added to each culture. At 72 h, the trichloroacetic acid-insoluble product was separated onto 0.45- μ m Millipore filters. The dried filters were put into a scintillation cocktail of 0.5 g PPO and 5 g POPOP per l toluene and counted overnight in a Packard Tri Carb Scintillation Counter. Cell surface oxidised lymphocytes were treated with 50 units ml⁻¹ neuraminidase for 30 min at 37 °C at a cell density of 20×10^6 cells per ml. Neuraminidase (EC 3.2.1.18 from *Vibrio cholerae* strain Z-4) was obtained from GIBCO as a solution containing 500 units ml⁻¹ where 1 unit releases 1 μ g of N-acetyl neuraminic acid from a glycoprotein substrate in 15 min at pH 5.5 at 37 °C. This was followed by treatment with 0.25 units ml⁻¹ galactose oxidase (Worthington) for 30 min at 23 °C at a cell density of 20×10^6 per ml. A unit is the quantity of enzyme that yields an absorbance of 1.0 at 420 nm by the peroxidase-chromagen assay. PHAMR 69 (Wellcome), con A (Calbiochem), colchicine (Sigma), and vinblastine (Lilly), were added to the cells just before they were put into culture. Each point represents duplicate cultures of 10 different donors. Data is expressed as the mean % of mitogenic control. Absolute c.p.m. for mitogenic controls were 68,500–122,300 for con A, 72,400–131,200 for PHA, and 58,400–118,600 for NG. Mean mitogenic controls were 102,500 for con A, 108,600 for PHA, and 87,400 for NG. ●, NG; ○, PHA; △, con A.

Table 1 Values for $-\log_{10}K_i^{50}$; K_i^{50} is the drug concentration inhibiting mitogenesis by 50%

are directly linked and necessary for lymphocyte activation to take place. No evidence exists to suggest that blocking membrane turnover, early RNA synthesis, or production of lymphotoxin leads to inhibition of lymphocyte activation. Furthermore, it has been shown that colchicine inhibits phosphatidylinositol turnover, another early cellular event, in con A-stimulated lymphocytes¹⁴.

It has been suggested that inhibition of mitogenesis by colchicine is due to blockage of thymidine transport. Wilson¹⁵ found the inhibition constant for blockage of thymidine transport by colchicine to be 6.1×10^{-5} M. Interestingly, in our experiments NG-mediated mitogenesis was not 50% inhibited by colchicine until levels of 5×10^{-5} M were reached. Thus for NG-mediated mitogenesis our results are consistent with, but do not prove, the hypothesis that the site of action of colchicine may be at the level of thymidine transport. Furthermore, saturation kinetics, consistent with competitive inhibition of transport were observed. In contrast, con A-mediated blastogenesis was 50% inhibited by 1×10^{-7} M colchicine and 4×10^{-8} M vinblastine, a concentration far too low to act at the level of thymidine transport. This is close to the purified tubulin affinity constant for adult human brain of 3.4×10^{-7} M (ref. 15).

It has been assumed until now that lectins and cell sur-

Fig. 2 Effect of colchicine on lymphocyte transformation. Experimental conditions were the same as for Fig. 1. Each point represents duplicate cultures of 10 different donors. Data expressed as in Fig. 1. ●, NG; ○, PHA; △, con A.

Fig. 3 Effect of cytosine arabinoside on lymphocyte transformation. Experimental conditions as for Fig. 1. Each point represents duplicate cultures of five different donors. Data expressed as in Fig. 1. ●, NG; ○, PHA; △, con A.

face oxidation result in a perturbation of the cellular membrane (perhaps cross-linking^{16,17}) that results in secondary triggering of the same cytoplasmic messenger. It may be, however, that a biological process as complex as mitogenesis is under multifactorial control. There is evidence that the initial membrane event for the two groups is different. Free aldehyde groups generated by cell surface oxidation do not seem to be generated by lectins since mitogenesis due to the former but not the latter stimulus is inhibited by reducing agents⁸. Our results show that although microtubules are necessary for lectin-mediated lymphocyte transformation, they are not a crucial intermediary in transfer of information from cell surface to the genome for cell surface oxidised cells.

Immunoglobulin binding to herpes virus-induced Fc receptors inhibits virus growth

WATKINS¹ reported that sheep red blood cells coated with anti-sheep-red blood cell antibody adsorbed to monolayers of herpes simplex virus (HSV) infected cells. Yasuda and Milgrom² suggested that the haemadsorption was mediated through an Fc-binding site which developed on the surface of the HSV infected cell, and later work from Watkin's laboratory established this interpretation³. Although the receptor for the Fc portion of IgG on the surface of HSV infected cells has been known for some time, its biological role remains unclear^{4–7}. We show here that when the HSV-induced Fc receptor is engaged with IgG or Fc fragments, viral replication is significantly inhibited.

Pools of HSV-2 (strain MS) were grown and titrated in Vero cell monolayers⁸. The Fc receptor studies were done with Vero monolayers and with a human retinoblastoma cell line (Y-79) which grows in suspension⁹. The cells were grown in RPMI 1640 medium (NIH) with 5% foetal calf serum (GIBCO). Fc receptors were demonstrated with sheep red blood cells coated with rabbit 7S antibody to sheep red cell stroma (7SEA). Sheep red cells coated with 19S antibodies were used as control reagents. Haemadsorption assays were done with minor modifications of previously described methods^{8,9}.

Both Vero and Y-79 cultures infected with HSV-2 contained 20–40% of the cells with Fc receptor 20 h after infection. No haemadsorption was seen in infected cultures with 19S-EA reagent, and uninfected cells were negative with both the 7S-EA and 19S-EA. In the Y-79 cultures infected at a multiplicity of 100, haemadsorption was first detected after 6 h, and by 8 h after infection the percentage of rosetting cells was equal to that detected 20 h after infection. Haemadsorption was inhibited when the infected cells were pre-incubated in balanced salt solution (BSS) containing 1 mg ml⁻¹ of IgG of different species (goat, rabbit, mouse). Haemadsorption inhibition was also achieved with Fc fragments but not with (Fab')₂ fragments of rabbit IgG. These results suggest that IgG and Fc fragments occupy the Fc binding sites at the surface of HSV infected cells. Furthermore radiolabelled IgG is known to bind to HSV infected cells³.

We next tested the effects of IgG on virus growth in these cells. The normal concentration of IgG in human serum is 12 mg ml⁻¹, so to avoid unphysiological levels we used concentrations of 1–10 mg ml⁻¹. Serum-free RPMI 1640 medium was prepared with DEAE-purified rabbit IgG in concentrations of 1, 5 and 10 mg ml⁻¹. The IgG used in all experiments was free of HSV neutralising activity in a standard viral plaque neutralisation test. Bovine serum albumin (Sigma) in 1, 5 and 10 mg ml⁻¹ concentrations was used as control medium. Cells were infected at a multiplicity of 100 for 1 h at 35 °C, washed twice in RPMI 1640, and transferred to IgG- or albumin-containing medium. They were incubated for 24–48 h at 35 °C and the total

virus in the cultures after three cycles of freezing and thawing was assayed on Vero monolayers.

As shown in Table 1, there was a 99% reduction in virus production in the cultures treated with 10 mg ml⁻¹ IgG. There was no inhibition of virus growth in 1 mg ml⁻¹ IgG. These results have been consistently reproducible both in Vero and Y-79 cells.

Although the concentrations of IgG we used were in the physiological range, we still thought it would be of importance to determine whether they were cytotoxic in our cell systems. We tested viability of non-infected Vero and Y-79 cells maintained in our 10 mg ml⁻¹ IgG medium for 24–48 h by Trypan blue exclusion and found no cytotoxicity.

We have also tested the effects of purified Fc fragments of rabbit IgG on virus growth. Rabbit IgG was digested with papain and the Fc fragments were purified by the method of Prahl¹⁰. When infected cultures were maintained in medium with 5 mg ml⁻¹ Fc fragments, virus production was 99% inhibited (Table 1). Similar inhibition was seen with Fc fragments at 2.5 mg ml⁻¹ and no effect was demonstrable with 1 mg ml⁻¹.

The infected monolayers of Vero cells maintained on IgG showed a marked decrease in viral cytopathic effect when examined by light microscopy. Electron microscopic examination of Vero and Y-79 cultures 24 and 48 h after infection in 10 mg ml⁻¹ IgG medium showed a marked decrease in viral capsids in the nuclei when compared to control cultures (Fig. 1). Most of the capsids in the IgG treated cells were empty, and accumulations of empty capsids in the cytoplasm were prominent. The same morphological findings were observed when the infected cultures were incubated in medium containing Fc fragments.

In all of the infected cultures examined by electron microscopy, the morphological effects on virus by IgG and Fc fragments were seen in more than 90% of the cells. Although only 20–40% of the cells in infected cultures produced rosettes with the 7S-EA, it is known that haemadsorption with 7S-EA is not an efficient method for demonstrating Fc receptors in other systems¹¹, and our electron microscopical findings suggest that the immunoglobulin exerts an inhibitory effect on most if not all infected cells in the cultures.

We also tested the effect of incubation in IgG containing media on infectious centre production. Y-79 cells were infected with a multiplicity of 100, washed three times in BSS and 10⁴, 10³ and 10² cells plated on Vero cell monolayers. After plating, the monolayers were fed with IgG-containing medium supplemented with 2% of HSV anti-serum in order to obtain plaques. This experiment showed

Table 1 Effect of rabbit IgG and Fc fragments on HSV growth in retinoblastoma and Vero cells

Retinoblastoma	Total virus produced (PFU ml ⁻¹)
IgG (10 mg ml ⁻¹)	2.3 × 10 ⁴
Fc Fragment (5 mg ml ⁻¹)	1.2 × 10 ⁴
Control	1.3 × 10 ⁶
Vero	
IgG (10 mg ml ⁻¹)	1.2 × 10 ²
Fc (5 mg ml ⁻¹)	1 × 10 ³
Control	2.5 × 10 ⁴

Cultures were infected at a multiplicity of 100 and viral growth was measured 24 h (Vero) and 48 h (retinoblastoma) after infection. Control cultures contained equivalent protein concentration of albumin. 10⁴ cells were infected with 10⁶ plaque forming units (PFU) and incubated in IgG or Fc fragment-containing media. At the end of the experiment the number of cells was not changed, indicating no loss of cells or growth during the experiment. The cell viability was 90% by Trypan blue exclusion in both controls and IgG treated cultures.

Fig. 1 Electronmicrographs of Vero cells infected with HSV-2. *a*, Cells incubated for 24 h in media containing albumin. Production of complete virions is seen. *b*, Cells incubated with 10 mg ml⁻¹ of rabbit IgG. Empty viral capsids are present in the nucleus and cytoplasm. ($\times 17,000$).

no infectious centres in IgG-containing medium with 10^4 , 10^3 or 10^2 cells while controls in medium free of IgG showed that 12% of the infected cells plated as infectious centres. The low percentage of infectious centres in the controls may be related to the use of a fluid rather than semi-solid overlay.

Our results establish that IgG and its Fc fragment inhibit the growth of HSV and strongly suggest that the effect is due to engagement of the virus-induced Fc receptor. Although the mechanism is not yet known, it is possible that this inhibition obtained with physiological concentrations of IgG may be of relevance in control of primary

infection *in vivo* and perhaps in the establishment or maintenance of latency.

We thank Dr M. Frank for preparation of sheep red blood cell reagents.

Excretion of feline leukaemia virus by naturally infected pet cats

THE transmission of feline leukaemia virus (FeLV) horizontally among cats has been well established¹⁻³ but the source of infectious virus responsible for this transmission has not been determined. C-type particles resembling FeLV have been seen by electron microscopy in many tissues and body fluids from cats having leukaemia and lymphoma⁴⁻⁷. In reference to potential environmental excretion, particles have been seen in the upper and lower respiratory tract, saliva, urine, gut wall, and peripheral blood. These studies, however, have been limited to electron microscopic visualisation and have not studied levels of infectious FeLV in tissues or fluids which could release virus into the environment. Speculation about the source of infectious virus has included urine, saliva, fleas, and blood (from either scratches, bites, or blood sucking arthropods)^{1,8}.

FeLV is so far the only oncogenic RNA virus that is known to be widely disseminated in man's environment, and several epidemiological studies have attempted to determine if an increased risk of human malignancies occurs for individuals exposed to leukaemic cats⁹⁻¹². Furthermore, the US National Cancer Institute has categorised the FeLV and the feline sarcoma virus as agents of 'moderate risk', presumably because they can grow in human cells and/or demonstrate oncogenicity in experimental conditions in certain non-feline species¹³. It thus seems remarkable that little or no information is available on the sources and amounts of infectious FeLV in excretory materials, especially from those taken from naturally infected pet cats.

To understand better the transmission of this disease and to assess the exposure potential of this virus to human contacts of infected cats we have studied the excretion of FeLV in virus-positive cats.

The animals used in all experiments were naturally infected FeLV-positive healthy pet cats who were identified from two sources: a previously characterised cluster house (four cats)¹⁴, or cats referred by community veterinarians (eight cats). The cats were judged positive based on the indirect immunofluorescence test for virus internal antigens in peripheral blood cells². Six of the animals were domestic short hair, three were Abyssinian, two Burmese, and one Siamese. Eight were males and four were females. All were asymptomatic and seemed healthy.

Plasma was collected in heparinised tubes, placed on ice,

separated, and frozen at -90°C until testing. Saliva was collected using small calcium alginate swabs (Calgiswabs, Inolex, Glenwood, Illinois), diluted in 1.5 ml medium and frozen at -90°C until testing. These swabs absorb a constant volume of saliva and allow quantification of infectious virus (unpublished observations). Urine was collected in sterile containers after manual expression from the bladder. Faecal specimens, in approximately 1-g amounts, were collected using calcium alginate swabs and placed in phosphate-buffered saline and frozen before testing at -90°C . After thawing, the suspension was centrifuged briefly at 1,000 r.p.m. and the supernatant was passed through a $0.22\text{-}\mu\text{m}$ filter (Millipore, Bedford, Massachusetts) before placing on cell cultures. Fleas were individually vacuumed off from cats, pooled in groups of ten, and frozen at -90°C until testing. Before being placed in cell cultures, the fleas were diluted in 1 ml cell culture medium, homogenised with a Teflon pestle, and centrifuged briefly at 1,000 r.p.m.

Fig. 1 Simultaneous FeLV titres in plasma (continuous line) and saliva (dotted line) in two cats (a and b) followed for 2 months.

Virus assay was carried out in triplicate using the method of Fischinger¹⁵. Before assay, all specimens were thawed, and tenfold dilutions were made on ice using McCoy's 5a with 15% foetal calf serum containing penicillin 100 IU ml^{-1} , streptomycin $100\text{ }\mu\text{g ml}^{-1}$, and amphotericin $0.25\text{ }\mu\text{g ml}^{-1}$.

Simultaneous saliva and plasma samples collected from nine cats were assayed for virus (Table 1). Saliva was positive in all cats examined, containing 5.4×10^3 – 3.9×10^5 focus forming units (f.f.u.) per ml whereas plasma generally contained about fivefold less. Three cats out of the twelve continued to excrete a cytopathic agent in their saliva for the entire length of the study and we were unable to assay their saliva for virus.

Urine was tested from three cats and was negative for infectious virus at the lowest dilution (undiluted or 1:10) (Table 2). Foecal specimens from three cats were tested, and no infectious virus was demonstrated at the

Table 1 Simultaneous saliva and plasma levels of infectious FeLV

†Mean.

lowest dilution (0.5 g ml^{-1}) (Table 2). Ten pools of ten fleas each were examined for infectious virus. None was demonstrated at the highest concentration (5 fleas ml^{-1}) (Table 2).

Two cats were followed for 2 months with once or twice weekly FeLV assay for plasma and saliva (Fig. 1). These cats regularly excreted high titres of FeLV in their saliva (10^4 – 10^6 f.f.u. ml^{-1}) and their plasma (10^3 – 10^5 f.f.u. ml^{-1}). Although there was moderate variation of both saliva and plasma, the titres of virus in both remained high and never dropped below 10^3 f.f.u. ml^{-1} . Plasma FeLV alone was assayed in four additional cats for 3 months. The results were similar to those shown in Fig. 1.

Our results indicate that FeLV-infected healthy cats excrete levels of infectious FeLV in saliva that are as high or higher than levels in blood plasma. Although various other tissues and body fluids have revealed virus particles by electron microscopy or serology, our negative results on these suggest that they may be less significant as sources of transmissible virus. In a previous serological study that was non-quantitative, we found detectable levels of FeLV in salivary gland tissue from five out of five leukaemic cats and in urine from three out of five leukaemic cats². Whether cats that are leukaemic excrete infectious FeLV in the same manner as healthy infected cats is unknown. Our study, however, has emphasised non-leukaemic FeLV-infected cats for two reasons: (1) the prevalence of such cats in most random pet populations is considerably higher than the number with leukaemia; and (2) non-leukaemic FeLV-excretor cats have been regularly overlooked or ignored by epidemiologists who examined either cat-to-cat or potential cat-to-man transmission. Such conventional epidemiological studies, especially those attempting to link feline leukaemia to human malignancy, have usually failed to detect horizontal transmission of FeLV or any increased risk of malignancy in human contacts^{12,16}. These investigations, however, chose cases and controls by pathological diagnosis or pet ownership status, and not by virus positivity. We now know that 10–50% of leukaemic cats ('cases') are non-viraemic^{1,2,17}, and that clinically healthy cats or those ill with diseases other than leukaemia or lymphoma ('controls') are often infected with FeLV. Also, serological studies have indicated that many FeLV-infected healthy cats contain detectable plasma virus for several years^{18,19}. In addition, as many as half of the pet cats in free-roaming

Table 2 Infectious FeLV titres in specimens from healthy excretor cats

Specimen	Cats tested	Total	Samples tested (f.f.u.)*	Mean titre (f.f.u.)	Range (f.f.u.)

‡Total of 100 fleas.

populations have evidence of transient FeLV infection, and only small proportions of those that remain chronically infected ultimately develop leukaemia or lymphoma^{1,20}. Therefore, epidemiological studies to date designed to ascertain human risk of FeLV exposure have not precisely done so since virus exposure was probably present in both the case and control groups.

In conclusion, it seems too early to rule out a link between any human disease and exposure to FeLV. Many FeLV-infected cats exist in the community and the laboratory methods to identify them are readily available. Subsequent studies designed to examine potential human risk from FeLV should compare the incidence of human disease in contacts of FeLV-positive cats to matched controls in FeLV-negative cats.

Blood group-like activity released by human mammary carcinoma cells in culture

TUMOUR cells synthesise and release antigenic membrane associated components which circulate either in a free state or complexed with host immunoglobulins¹⁻⁵. A membrane derived N-like glycoprotein, which inhibited *Vicia graminea* lectin haemagglutination, has been demonstrated in serum and ascites fluid of mice bearing the Ha subline of TA₃ murine mammary adenocarcinoma⁶. Springer *et al.*⁷ have shown that M and N blood group reactive substances were present in both benign and malignant lesions of the human breast. But, T-like *Arachis hypogaea* reactive substances were only found in malignant breast tissue and not in benign tumours or healthy breast tissue⁷. Isolation and long term cultivation of a human mammary tumour cell line, BOT-2 was recently reported⁸. Immunological tests indicated that women with diagnosed mammary cancer had circulating antibodies that reacted with these cells⁹ and induced cell surface shedding¹⁰. Here we report the use of blood-typing antisera and lectins to characterise the proteins synthesised and spontaneously

released from BOT-2 cells growing in defined medium. To our knowledge this is the first demonstration of M, N, T, Tn erythrocyte-like glycoproteins being spontaneously shed from human epithelial tumour cells in culture.

BOT-2 cells, after 2 d growth on Eagle's minimum essential medium with 10% foetal calf serum, were grown to confluency (2 weeks) in albumin containing, serum free medium (Hi-WO₃/BA₂₀₀₀; International Scientific). After the 2-week interval, each third day the medium was collected from the culture flasks, centrifuged at 200g for 10 min to remove debris and lyophilised. The dry solids were resuspended in distilled water, dialysed against phosphate buffered saline pH 7.2 (PBS) and chromatographed on Sephadex G-10 equilibrated with PBS. The G-10 excluded proteins were then concentrated to 5 mg ml⁻¹ by pressure dialysis on an Amicon XM-50 membrane. The concentrated protein was tested for reactivity against human blood-typing lectins and antibodies. First the BOT-2 protein was screened for reactivity against various lectins by double diffusion in gel. Then, more sensitive agglutination inhibition assays were performed to show the competition of BOT-2 proteins and M or N red cells for specific anti-M or N antibody binding. Finally because of the potential significance of spontaneously shed glycoproteins with T-like activity to tumour growth and survival, a more sensitive test using shed proteins to inhibit T-erythrocyte agglutination was used.

Double diffusion reactions of BOT-2 proteins and selected blood group typing lectins are shown in Table 1. It may be seen that BOT-2 proteins formed precipitin bands with a variety of lectins having specificities related to blood group antigens M, N, T and Tn. To show cross-reactivity of BOT-2 proteins and the erythrocyte glyco-

Table 1 Blood group active lectins which form precipitin bands with shed human breast tumour cell proteins

Blood group		Lectins	
Activity	Common name	Systematic name	Refs
anti-M	Candytuft	<i>Iberis amara</i>	11, 12
anti-N	—	<i>Vicia graminea</i>	7, 11
anti-T	Peanut	<i>Arachis hypogaea</i>	11, 13
anti-Tn	Blue beard	<i>Salvia horminum</i>	14
anti-Tn	Horse gram	<i>Dolichos biflorus</i>	7

Seeds were ground dry, mixed with four times their weight of 0.15 M NaCl for 3 h at 20 °C, centrifuged 10 min at 3,000g and the supernatant solution collected. *A. hypogaea* lectin was further purified by affinity chromatography on β -galactosyl derivatives coupled to Sepharose 4B. The lectins (5–20 mg ml⁻¹) were reacted with a 10X concentrate (5 mg ml⁻¹) of dialysed BOT-2 cell growth medium by diffusion tests in 1% Agarose in PBS¹⁵.

proteins by a system involving different reaction mechanisms, a specific antiserum-red cell agglutination inhibition was performed. Agglutination of human M and N erythrocytes by both human and rabbit anti-M and anti-N antisera was inhibited by BOT-2 proteins (Table 2). When a more sensitive assay of T-like activity in BOT-2 proteins was used, the agglutination of human T red blood cells (neuraminidase-treated erythrocytes) by anti-T lectin (*A. hypogaea*) could be completely inhibited by BOT-2 proteins (Table 3). Inhibition required 3,000 times as much BOT-2 proteins as anti-T lectin on a weight basis, however.

In all assays two types of controls were performed. In one, unused medium was concentrated to equal the concentration of medium from BOT-2 cells. In the other, growth medium from a human melanoma cell line was prepared in the same manner as the BOT-2 proteins. When the concentrated unused or melanoma growth medium were tested by double diffusion, antibody agglutination inhibition or lectin agglutination inhibition, no M, N, T or Tn activity was found.

Shed glycoproteins from human breast carcinoma cells

Table 2 Effect of shed human breast tumour cell proteins on the agglutination of M or N erythrocytes by human and rabbit M or N antiserum

Erythrocytes and antiserum	Human antiserum BOT-2 cell proteins (μ g)	Inhibition of agglutination	Erythrocytes and antiserum	Inhibition of agglutination
M	65	Yes	M, 1:2	No
M	32	No	M, 1:4	No
M	16	No	M, 1:8	Yes
			M, 1:16	Yes
N	65	Yes	N, undiluted	No
N	32	No	N, 1:2	Yes
N	16	No	N, 1:4	Yes

Using human antiserum, 50 μ l of serum were incubated with 50 μ l of the indicated amount of BOT-2 cell proteins. Using rabbit antihuman M or N antiserum, 25 μ l of serum at the indicated dilutions were incubated with 25 μ l (32 μ g) of BOT-2 cell proteins. After 15 min incubation at 20 °C, 25 μ l of a 3% suspension of washed human M or N erythrocytes were added to the reactions. After incubation for 90 min, the agglutination reactions were read by visual inspection. The haemagglutination titres of the human M and N antisera were both 1:8. The haemagglutination titres of the rabbit M and N antisera were both 1:64.

in culture react with the same lectins as do the membrane antigens isolated from whole human breast tumour tissue⁷ and the glycoproteins in serum and ascites fluid from mice bearing the TA₃-Ha mammary carcinoma⁶. The finding that BOT-2 glycoproteins reacted with anti-M lectin (*I. amara*) and anti-N lectin (*V. graminea*) suggests that the carbohydrate portions of BOT-2 proteins are similar to that of M and N blood group substances. The reaction of BOT-2 proteins with anti-T (*A. hypogaea*) and anti-Tn (*S. horminum*, *D. biflorus*) may be due to incomplete glycosylation of some of the carbohydrate chains by BOT-2 cells, since T and Tn activity may be induced from N substance by selective enzymatic digestion¹⁶⁻¹⁹.

Other workers have found M and N activity in both benign and malignant breast tumours, but T and Tn activities have been reported to occur only in malignant human breast tumour tissue. A significant number but not all patients with active mammary carcinomas had lowered anti-T serum activity, but after surgical excision of the tumour many of these patients had increased serum anti-T activity²⁰.

Our findings show that a human ductal mammary carcinoma cell line growing in chemically defined media spontaneously releases glycoproteins which have M, N, T and Tn activity. These observations are in accord with the idea that early survival of these cells may depend on presentation of a cell surface similar to M and/or N erythrocyte membrane glycoproteins. As the tumour mass increases it ceases to form fully glycosylated membrane glycoproteins. The resulting incompletely glycosylated M-N precursors (that is, T and Tn) may block or overwhelm the hosts immune capabilities with the result that rapidly growing and aggressive tumour cells have decreased restraint upon survival and growth.

We thank R. J. McNeil, P. J. Riggs, and P. L. Munson for technical assistance; Dr Jim Lawson, Tulsa Regional Red Cross Blood Center, for useful conversations and

the gift of some seeds; Richard Murdock (Ortho Pharmaceuticals) for human M and N antisera; Bill Deal and Twanda Bruegggen for typed blood; and the American Cancer Society (BC-230) and the Maizie Wilkonson award for support.

A-specific autoantigenic ovarian glycolipids inducing production of 'natural' anti-A antibody

ACCORDING to current concepts, those antibody populations which appear spontaneously in the sera of many species against components of the widely-distributed ABH (blood-group) antigen system are due to stimulation by corresponding exogenous (environmental) antigenic material¹⁻³. We present here evidence which strongly suggests an alternative origin in the mouse.

We recently reported that the development of 'natural' antibodies against structural elements of the common (blood-group) antigen A is markedly sex-dependent in C57BL/10 inbred mice. In these experiments all the sera of

Table 3 Effect of shed human breast tumour cell proteins on the agglutination of human T erythrocytes by purified anti-T lectin

BOT-2 cell proteins (μ g)	Agglutination of T erythrocytes
300	No
150	No
75	Yes
38	Yes

Human T erythrocytes were prepared by neuraminidase treatment of human O erythrocytes⁷. Purified anti-T lectin (*A. hypogaea*) 50 ng was incubated for 15 min at 20 °C with the indicated amount of shed proteins from BOT-2 cells; 0.2 ml of a 3% suspension of T erythrocytes was then added and the mixture incubated for 90 min. The agglutination reaction was determined by visual inspection. The haemagglutination titre of the peanut lectin was 1:10,000.

the females of healthy, unvaccinated mice displayed high levels of antibodies which selectively agglutinate the erythrocytes of the human blood group A, but only about 50% of the sera of the males exerted detectable activities. This pronounced production of 'natural' anti-A antibody in females having a normal oestrous cycle and fertility correlates with the synthesis of ovarian glycolipids specifically combining with the syngeneic 'natural' anti-A antibody, which they strongly inhibit. Such auto-reactivity was not detected in the glycolipid fractions from any of the other male and female murine tissues at statistically significant levels¹. Moreover, anti-A specific complement-dependent lytic serum activities which discriminate between different (blood-group) A-antigen expressions or qualities and are also exclusively inhibited by the syngeneic ovarian glycolipids could be demonstrated in a further study², and similar observations have been made in limited (unpublished) studies with DBA/2, DDS and NMRI mice.

The genetic background of these findings is as yet unknown, and the site of appearance of the A-active glycolipid structures in the ovarian tissue and the type of cell or cells engaged in their production could up to now also not be determined. But the experiments presented here (Fig. 1) show that these glycolipid structures are probably not expressed at birth but appear during post-natal ovarian maturation and that only low levels of the 'natural' anti-A antibody are produced in the absence of the ovary. At 10 d of age the murine ovarian tissue displays extremely weak A-specific auto-reactivity which then increases rapidly during the maturation process. Marked auto-reactivity can already be measured at the age of 20 d, that is, long before the first ovulation, but complete expression of this reactivity is not reached before the age of 30–40 d and thus correlates with the onset of puberty in the mouse. In fact, no further increase could be measured thereafter. This is illustrated in Fig. 1a, which also shows that the development of the A-specific auto-reactive structures markedly precedes the appearance of the anti-A antibody (Fig. 1b). The antibody develops poorly in mice ovariectomised at the age of 20 d, whereas the development of the antibody levels in sham-operated mice does not significantly differ from that in non-operated mice. Hence, the 'natural' anti-A antibody in the C57BL/10 female mouse is an autoantibody, that is, the syngeneic ovarian glycolipids not only combine with this antibody as a result of, for example, coincidental cross-reactivity, but are also specifically engaged in its induction.

The crucial carbohydrate determinant of these glycolipids involves *N*-acetyl-D-galactosamine in terminal linkage, as the glycolipid material prepared by the method previously described¹ strongly inhibits the agglutinins specifically combining with this amino sugar. Four haemagglutinating units of the anti-A specific lectin from *Dilochos biflorus* (Behringwerke) and the anti-A haemagglutinin from *Helix pomatia* (from Dr E. Cohnen) in volumes of 20 μ l were incubated with equal volumes from twofold serial dilutions of the ovarian glycolipids in 130 mM NaCl–25 mM Na-phosphate buffer, pH 7.2 (PBS), for 60 min at 24 °C. Twenty μ l of a 1% suspension of washed human blood group A₁ erythrocytes in PBS were then added and the incubation was continued for another 60 min. The amounts of the glycolipids producing complete haemagglutination inhibition were determined by microscope. The four haemagglutinating units of the *D. biflorus* lectin and the *H. pomatia* haemagglutinin were completely inhibited by 5 and 2.5 μ g of the glycolipid material respectively.

Whatever their other structural properties, which are currently being investigated, such glycolipids are probably not restricted to ovarian tissue. Moreover, the auto-reactive structures discovered in the ovary may also be produced in other murine tissues but in quantities too low to be

Fig. 1 *a*, Age-dependent appearance of ovarian A-specific auto-reactivity. 10-, 20-, 40-, 60- and 80-d-old healthy, unvaccinated C57BL/10 female mice from our colony (from Jackson Laboratory, Bar Harbor, Maine), each age group consisting of 3 × 20 animals, were killed by ether inhalation in three separate experiments. Whole venous blood was drawn from the caval veins of the 80-d-old mice, pooled, and the serum to be used in the inhibition experiments 'inactivated' for 15 min at 56 °C. The ovaries were removed and pooled according to the respective groups. The ovarian polar glycolipids were prepared as previously described¹ and dissolved in 130 mM NaCl–25 mM Na-phosphate buffer, pH 7.2, at 100 μ g ml⁻¹. The anti-A-inhibitory activities of the glycolipid material from the ovaries of the different age groups were measured and are given as % inhibition of the haemagglutinating power of the pooled syngeneic serum from the 80-d-old C57BL/10 females for human blood group A₁ erythrocytes according to the previously described quantification procedure¹. Values represent the arithmetic mean and standard deviation obtained from the three different inhibition experiments. *b*, Age-dependent appearance of 'natural' anti-A antibody activities in the sera of unvaccinated C57BL/10 female mice. \blacktriangle , Untreated (non-operated) mice; \square , mice ovariectomised at the age of 20 d; \circ , sham-operated mice. Animals to be ovariectomised or sham-operated were anaesthetised by intraperitoneal injection of 0.1 ml (40 mg per kg body weight) of pentobarbital sodium (Nembutal, C. H. Boehringer). Ovaries were removed by standard techniques. In sham-operations performed in parallel, the peritoneal cavity was opened and closed, but the ovaries were left intact. Three different groups, each consisting of 3 × 20 ovariectomised and 3 × 20 sham-operated animals, were killed on the day of the operation and at the age of 40, 60 and 80 d in three separate experiments. Corresponding groups of non-operated animals were killed in parallel. The sera were prepared from blood drawn from the caval veins, pooled according to the respective groups and 'inactivated' for 15 min at 56 °C. The anti-A haemagglutinin activities were determined using human blood group A₁ erythrocytes¹. Each value represents the arithmetic mean and standard deviation obtained from the three different experiments. Values on ordinate derived from¹

$$\sum_{i=1}^k [\text{score}_i \times (-\log_2 (\text{dilution}) + 1)]$$

demonstrable by the methods used in our previous studies^{4,5}. The low anti-A antibody levels in the sera of the males described in those studies and in the sera of ovariectomised females (see Fig. 1b) could reflect extra-ovarian autoantigenic structures, although the possibility of extraneous stimulation due to environmental A-antigenic components cannot be excluded.

Nevertheless, the data presented here strongly suggest that the production of the 'natural' anti-A antibody in the female mouse originates predominantly from autoimmunisation due to an ovarian autoantigen characterised by the A-specific auto-reactivity discovered. It could be argued that this autoimmunisation is induced by material released from the autoantigenic ovarian structures, but that these structures are probably not available to the antibody *in situ*. In fact, many potentially immunoreactive glycolipids in mammalian cell membranes are effectively shielded by proteinaceous cover and do not react with the antibodies directed against them. This applies particularly to a variety of globosides which display N-acetyl-D-galactosamine residues demonstrating predominantly Forssman-type specificity and becoming available to their corresponding antibodies only after protease treatment of the cell surface^{6,7}. Although the murine ovarian A-like autoantigen does not seem to involve this particular 'classic' heterophile specificity, its components might also well be 'masked' *in situ* and protected from immunological attack in normal conditions. Thus the functional significance of the findings reported is still not known. Moreover, the intriguing question of whether these findings may be extrapolated to other species and whether the majority of human 'natural' anti-A (iso)antibody populations may also basically reflect growth processes requires further investigation.

Reconstruction of photoreceptor membrane potentials from simultaneous intracellular and extracellular recordings

INSERTING a microelectrode into a cell to record electrical events provides a rapid and direct way of investigating many fundamental membrane-based processes^{1,2}. The intracellular signals so obtained do not, however, represent a true picture of the underlying permeability changes if significantly large extracellular potentials are also present. As this is indeed the case in a wide range of tissues, including the cephalopod retina, we have recorded simultaneously the intracellular (V_i) and extracellular (V_e) signals from the photoreceptors of *Sepiolo atlantica* in order to reconstruct the true transmembrane potential (V_m). We show here that the discrepancies between

V_i and V_m depend both on the magnitude and duration of the light stimulus.

Extracellular potentials of the order of 30 mV have been recorded from arthropod^{3,4} and cephalopod retinas (R. B. Clark and G.D., unpublished). These are set up by currents passing through regions of high resistance in the restricted space between adjacent photoreceptor cells (Fig. 1), and several equivalent circuit models that take account of this have been put forward⁵⁻⁶. One implication of these models, which has often been overlooked, is that, when the potential at the back of the eye is used as a reference point, the intracellular recording (V_i) will not give a true picture of the actual photoreceptor membrane potential change (V_m), but will in fact measure V_m in series with V_e (Fig. 1). As most investigators of both invertebrate and vertebrate retinas use this recording arrangement (see refs 1 and 2 for reviews), we felt it worthwhile to find out whether there are significant differences between observed V_i and computed V_m potentials (Fig. 1).

We have found that the most stable intracellular recordings are obtained from the cephalopod when the electrode enters a cell almost immediately after touching the distal surface of the retina. Before entering a cell, we first ensured that the extracellular signals from both recording

Fig. 1 Diagrammatic representation of a cephalopod photoreceptor cell based on the electron micrographs of refs 18 and 19. There is a minimal extracellular space between cells, whereas in the vertebrate retina the rods and cones are smaller and more widely spaced²⁰. The equivalent circuit is essentially the same cephalopod model as in ref. 6 and resembles an arthropod model⁴. The sodium resistance (R_{Na}) in the distal segment is assumed to decrease in the light. Photocurrents (I) flowing across a large extracellular resistance (R_e) imply a correspondingly large V_e . R_K is usually assumed constant and R_i small, but the validity of neither of these assumptions affects our basic argument which is that the intracellular signal (V_i) does not give a true measure of the primary transmembrane voltage change (V_m). In the recording arrangement used here with the reference electrode (in this case a silver/silver chloride wire loop) at the back of the retina, V_m is given by the difference between V_i and V_e . As V_i and V_e have opposite signs, this means in effect adding the amplitudes of the signals in order to reconstruct V_m .

electrodes were identical. The fact that we could do this with electrodes that were spaced at least 1 mm apart showed the homogeneity of the illumination conditions and, more importantly, the homogeneity of radial current flow across the retina.

Simultaneous extracellular and intracellular records were obtained in response to both short and long flashes from the non-perfused retina maintained at 10 °C (see ref. 7 for experimental details). The short flashes from a stroboscope were 10 μ s in duration and so were well within the latency period of the response at all intensities (Fig. 2). At low intensities ($\log I = -3.2$ and below), the time courses of the two signals are similar whereas the amplitude of the intracellular is the larger. Thus, over this intensity range, the intracellular signals are representative of the true transmembrane potential changes. At higher intensities, the two responses have different time courses and are of comparable magnitude. They are complementary in that they sum algebraically to give a flat region of maximal amplitude. This becomes more apparent as the intensity increases.

The recovery to the baseline is complete within 500 ms at low intensities, whereas there is a significant delay in recovery at the higher intensities. This after-depolarisation, which has been observed in a number of invertebrate preparations^{8,9}, increases with increasing intensity. In vertebrate rods and cones there is an after-hyperpolarisation which increases with intensity¹⁰⁻¹². At the highest intensity used in the present study ($\log I = 0$) there is a very pronounced transient phase in the intra-

Fig. 2 Response to short flashes. Simultaneous recordings of intracellular and extracellular photoreceptor potentials of the cephalopod retina. The beginning of each trace (arrowed) corresponds to the arrival of a 10- μ s xenon tube flash of unfiltered incident energy equal to 10^{-2} J m $^{-2}$ of white light ($\log I = 0$). The relative intensity of each flash is given on the left of the figure. The resting potential was -45 mV in all of the intracellular recordings (depolarising upwards). The dark potential in the extracellular recordings was zero and an upward deflection in this case corresponds to a negative-going potential at the microelectrode. The signals were digitised, filtered above 1 kHz and plotted. The horizontal scale bar represents 150 ms and the vertical bar represents mV, which for the various intensities is given (in the sequence V_i , V_e , V_m) as follows: $\log I = -5.2$: 0.4, 0.3, 0.7; $\log I = -4.6$: 1.5, 1.0, 2.4; $\log I = -3.8$: 3.6, 2.8, 5.9; $\log I = -3.2$: 6.8, 5.7, 12.1; $\log I = -2.8$: 8.2, 7.6, 15.6; $\log I = -2.3$: 8.8, 9.1, 17.4; $\log I = -1.8$: 9.2, 9.6, 17.7; $\log I = -1.21$: 9.5, 9.7, 17.4; $\log I = 0$: 9.4, 11.1, 16.6.

Fig. 3 Response to long flashes. Responses to 500-ms flashes from a light-emitting diode (Plessey GPL5). The light from the diode had an unfiltered energy equal to 0.02 W m $^{-2}$ ($\log I = 0$). The start of each trace corresponds to the stimulus onset which had virtually zero increase-time. The stimulus duration is marked by the solid line below each column. The intracellular dark-adapted potential was -42 mV in each case and the extracellular dark potential was zero. The horizontal scale bar represents 250 ms and the vertical scale bar (mV) for each of the light intensities is given (in the sequence V_i , V_e , V_m) as follows: $\log I = -2.56$: 0.6, 0.2, 0.8; $\log I = -1.96$: 1.3, 0.4, 1.7; $\log I = -1.2$: 3.4, 1.3, 4.7; $\log I = -0.73$: 5.5, 2.3, 7.4; $\log I = -0.32$: 6.7, 3.1, 9.4; $\log I = 0$: 6.8, 3.9, 10.1.

cellular recording which corresponds very closely in time course to the fast response in the extracellular recordings (R. B. Clark and G.D., unpublished). An initial transient has been observed in *Limulus* photoreceptors when short intense flashes were used^{13,14}, and it has been suggested that the transient phase arises from a different mechanism from the remainder of the response¹⁴. It is interesting that the initial transient of V_i in the cephalopod almost completely disappears in the reconstructed membrane response (Fig. 2).

A light-emitting diode was used to deliver 500-ms flashes and in this case the waveforms of the intracellular and extracellular responses appear quite different (Fig. 3). The V_i records are much more rectangular in appearance, and the amplitudes of the responses of V_i were consistently greater than the corresponding V_e records. On closer examination, however, certain similarities between the two types of records emerge. The latencies of both the intracellular and extracellular signals at any one intensity are equal and decrease with increasing intensity, and the initial rate of increase of both signals increases with increasing intensity. At high intensities the intracellular response reaches a maximum value and then decays towards the baseline while the stimulus is still on. This 'sag phase' has also been observed in vertebrate rods and cones¹⁰⁻¹². In the cephalopod, it disappears in the reconstructed membrane responses (Fig. 3). The intracellular records again show a maintained after-depolarisation, which is relatively greater in magnitude than the offset in the V_e records. At high light intensities, as in the short flash responses (Fig. 2), the intracellular and extracellular records sum algebraically to give a flat response over a region in time where both V_i and V_e are changing.

Large extracellular responses are not unique to the invertebrate retina as vertebrate retinal neurones, principally Müller cells¹⁵, can in certain circumstances contribute several millivolts to the overall electroretinogram.

Some workers in this field do take precautions to prevent contamination of primary intracellular photoreceptor recordings by extracellular potentials¹². Extracellular potentials of comparable magnitude are also found, for example, in vertebrate cardiac muscle¹⁶ and olfactory tissue¹⁷. If the membrane events in these tissues are to be analysed in detail, for example in terms of current carriers and permeability changes, then it is important to know the basic time course of the potential change across the receptor membrane. The data presented here strongly indicate that both the intracellular and extracellular signals have to be recorded simultaneously in order to obtain this information. It is also true that in such tissues where the extracellular signal is a function of position (ref. 7 and R. B. Clark and G.D., unpublished), there is no single, true transmembrane potential, but in fact a continuum of transmembrane potentials that require simultaneous recording of the signals from an intracellular electrode and several extracellular electrodes placed at different depths in the tissue. Reconstructions of the primary photoreceptor membrane events based on a simple equivalent model such as that described in Fig. 1 and also a more complex model that takes account of the depth variation of the extracellular signal, will be the subject of a future communication.

We thank Professor E. Rojas and Dr P. C. Croghan for discussions, and Professor P. Fatt of University College for useful criticisms of the manuscript. P.B.P. acknowledges assistance in the form of a scholarship from the University of East Anglia.

Immunological identification of rat neurophysin precursors

NEURONES in the supraoptic and paraventricular nuclei of the hypothalamus synthesise two peptide hormones, vasopressin and oxytocin. These hormones and their neurophysin 'carrier' proteins are stored in (and released from) nerve endings in the posterior lobe of the pituitary^{1–3}. On the basis of extensive studies of the synthesis of vasopressin *in vivo* and *in vitro*, Sachs *et al.*^{4–8} have suggested that vasopressin and its associated neurophysin are synthesised as parts of a common precursor by a ribosomal mechanism. We have also presented evidence that the neurophysins are synthesised as parts of larger precursor molecules^{9,10}. These 20,000 molecular weight precursors seem first to give rise to 17,000 molecular weight intermediates which, in turn, yield the 12,000 molecular weight neurophysins. The following data show that the putative neurophysin pre-

cursors and intermediates bind specifically to anti-rat neurophysin antiserum.

Female Osborne-Mendel rats (250 g) were used. For 5–7 d before use, the rats were given 2% saline to drink to stimulate neurophysin and vasopressin biosynthesis¹⁰. They were then anaesthetised with ether and their heads were fixed in a stereotaxic device. The tips of two 30-gauge needles were positioned just adjacent to the two supraoptic nuclei^{9,10} and 20 μ Ci ³⁵S-cysteine (New England Nuclear; specific activity 40–50 Ci mmol⁻¹) in 1 μ l normal saline containing 1 μ g dithiothreitol were injected through each needle over a 5-min period. The rats were decapitated after an additional 55 min and their brains were quickly removed, mounted on specimen holders, and frozen on dry ice. The brains were placed in a cryostat (–9 °C) and 300 μ m thick frontal sections through the anterior hypothalamus were cut with a microtome. The supraoptic nuclei were dissected from the frozen sections with hollow, stainless steel needles¹¹. The tissue was immediately homogenised in 0.1 M HCl. Tissue pellets from ten animals were pooled into one sample, the final volume of which was 100 μ l. This sample was centrifuged at 10,000g for 5 min, and 10 μ l of the supernatant were subjected to isoelectric focusing in polyacrylamide gels (Fig. 1, solid line)^{10,12}. Four major peaks of labelled protein were present in the supernatant. These had isoelectric points (pI) of 5.1, 5.4, 5.6, and 6.1. A fifth peak (pI 6.9) was also consistently found, but it had less radioactivity than the others. We have previously reported that the pI 5.4 and 6.1 'precursor' proteins—the first ones to be labelled in the pulse-chase paradigm—have molecular weights of about 20,000 and that the pI 5.1 and 5.6 'intermediates' have molecular weights of about 17,000.

The remaining 80 μ l of the supernatant were neutralised with an equal volume of 0.1 M NaOH. An additional 200 μ l of 'buffer A' (0.01 M potassium phosphate, 1.5 M sodium chloride, 1% sodium azide, pH 7.4) were added plus 100 μ l of normal rabbit serum and 0.5 mg of bovine serum albumin. After 4 d at 4 °C the solution was passed over a calibrated Sephadex G-100 column (0.6 \times 17.5 cm) which had been equilibrated with buffer A. Some radioactive material which must either have been of large molecular weight or bound to large serum components appeared in the void volume of the column (Fig. 2a). Analysis of the radioactive substances in the void volume by isoelectric focusing indicated that relatively little of it was 'precursor' or 'intermediate'.

A major peak of labelled material eluted between 2.6 and

Fig. 1 Isoelectric focusing of ³⁵S-labelled proteins in an acid extract of the supraoptic nucleus 1 h after injection of ³⁵S-cysteine adjacent to this nucleus (solid line), and of labelled proteins in the above extract bound by anti-rat neurophysin (broken line). Six per cent polyacrylamide gels were used for isoelectric focusing; the sample buffer contained 8 M urea, 1% Triton X-100, and 2% ampholytes (pH 3–10); and the sample was loaded at the anodal end of the gel.

4.0 ml. Another very large peak came off the column after the bed volume (5 ml), and probably contained cysteine and peptides. A sample containing the material which eluted from the column between 2.9 and 3.5 ml (the '20,000 molecular weight peak') was divided into three 200- μ l aliquots. A specific and well characterised rabbit anti-rat neurophysin (20 μ l)¹³ was added to one of these plus 250 μ l of buffer A; 20 μ l of anti-rat neurophysin plus 20 μ g of rat neurophysin (prepared as described previously¹³) in 250 μ l of buffer A were added to the second; and 20 μ l of normal rabbit serum were added to the

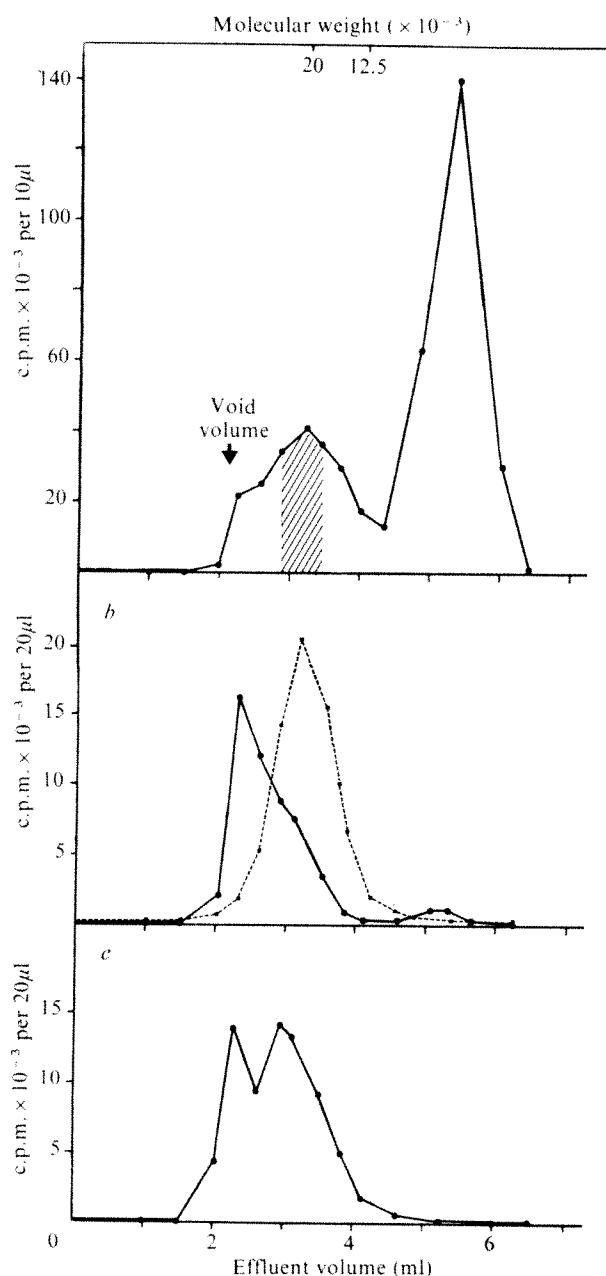

Fig. 2 Sephadex G-100 chromatography of ³⁵S-labelled material extracted from the supraoptic nucleus 1 h after a pulse of ³⁵S-cysteine. *a*, Separation of material which binds non-specifically to large molecular weight components of normal rabbit serum. Large, labelled molecules and smaller molecules bound to large species are found in the void volume. 'Precursors' and 'intermediates' are present in an included volume peak, the middle of which (hatched area) was used for subsequent studies. *b*, Most of the material in the included ('20,000 molecular weight') peak is excluded from the column after addition of rabbit anti-rat neurophysin (solid line). Addition of normal rabbit serum (broken line) caused no change in the elution pattern of the '20,000 molecular weight peak'. *c*, In the presence of rat neurophysin, some labelled protein in the '20,000 molecular weight peak' is excluded from the column (bound to antibody) and part is not.

third. Four days later the three samples were passed in turn over the G-100 column. Few counts appeared in the void volume of the column when normal rabbit serum was added to the '20,000 molecular weight peak'. The labelled material eluted where it had earlier (Fig. 2*b*), and less than 5% of it could be precipitated by adding goat anti-rabbit IgG. On the other hand, about 75% of the labelled material was found in the void volume of the column when anti-rat neurophysin was added to a sample of the '20,000 molecular weight peak' (Fig. 2*b*). The labelled species in the void volume could be precipitated in this case by goat anti-rabbit IgG, showing that they were attached to antibody. The antibody-bound materials that eluted between 2.0 and 2.3 ml were precipitated with trichloroacetic acid and subjected to isoelectric focusing. Four peaks were found with isoelectric points corresponding to those of the 20,000 molecular weight precursors ($pI = 5.4-6.1$) and the 17,000 molecular weight intermediates ($pI = 5.1-5.6$) (Fig. 1, broken line). The pI 6.1 protein seemed to be bound preferentially; the reason for this is unclear. A small amount of pI 6.9 protein may have been bound by the antibody; none of the other components of the original homogenate appeared to be bound.

The counts in the sample of '20,000 molecular weight peak', to which both anti-rat neurophysin and rat neurophysin were added, were distributed between a void volume peak and a 20,000 molecular weight included volume peak (Fig. 2*c*). The counts in the former peak were precipitated by anti-IgG; the counts in the latter were not; the neurophysin seems to have displaced labelled proteins from the antibody. The displacement may, however, have been incomplete because of (1) the presence of an excess of antibody relative to the amount of neurophysin added or (2) the relatively high affinity of the antibody for the precursors as opposed to neurophysin.

We have shown that, in addition to binding neurophysins¹³, anti-rat neurophysin antiserum binds four larger cysteine-rich proteins found in the supraoptic nucleus. These proteins, which do not react with immunoglobulins in normal rabbit serum to a significant extent, can be displaced from anti-neurophysin by neurophysin itself. These data lend credence to our suggestion that larger protein species synthesised in the supraoptic nucleus give rise to the neurophysins^{9,10}.

We have also studied the synthesis of neurophysin in a strain of rats with diabetes insipidus, that is, the Brattleboro strain¹⁴. These animals do not make vasopressin or its associated neurophysin. They lack the pI 4.8 neurophysin as well as the pI 6.1 precursor and the pI 5.6 intermediate. Thus, the vasopressin-associated neurophysin seems to be made from the pI 6.1 precursor by way of the pI 5.6 intermediate, and the oxytocin-associated neurophysin seems to be made from the pI 5.4 precursor by way of the pI 5.1 intermediate. Whether the precursors or intermediates are glycoproteins as are those of ACTH¹⁵ remains to be determined. Whether the precursors contain oxytocin and vasopressin as well as the neurophysins can now be tested directly.

Several of the adenosine deaminase isozymes are glycoproteins

THE basis for the complex multiple molecular forms (isozymes) of the enzyme adenosine deaminase (ADA) has been widely studied. The ADA found in human erythrocytes (so-called 'red cell' ADA) exhibits genetically determined polymorphism detectable by electrophoresis¹, has reactive thiol groups² and has a low molecular size³. 'Red cell' ADA is present in various tissues other than the red cell³, but additional adenosine deaminases, the so-called tissue ADA isozymes *a*, *b*, *c*, *d* and *e* named in order of decreasing electrophoretic mobility, which exhibit rather different properties, occur in varying amounts in nonerythroid tissues. With the discovery that the deficiency of 'red cell' ADA in certain patients with combined immune deficiency disease is accompanied by the deficiency of all the other isozymes⁴⁻⁶, it became clear that all the forms were probably coded by a single ADA locus. The 'red cell' ADA can be converted into the characteristic 'tissue' isozymes by tissue extracts both from normal individuals^{7,8} and from patients with combined immune deficiency disease. A converting factor has been isolated and partially purified and is thought to be a protein⁹. This protein is presumably associated with one or several 'red cell' ADA molecules to form the 'tissue' isozymes, accounting for the alteration in properties (increase in molecular size, loss of detectable genetically determined electrophoretic variation and loss of thiol reactivity³). We present here evidence, from lectin affinity chromatography and experiments with neuraminidase, that most of the multiple forms of 'tissue' ADA are glycoproteins which differ in their accessible sugar residues. This suggests that the converting factor may be a single glycoprotein with heterogeneous carbohydrate content.

Treatment of extracts of various human tissues with the enzyme

neuraminidase (sialidase) seems to result in the conversion of the most anodal tissue ADA isozymes (*a*, *b* and *c*) into a zone of activity (*d*₂) which is slightly less anodal than the major *d* isozyme (now referred to as *d*₁). The effects of neuraminidase are most easily demonstrated using extracts of liver (Fig. 1) which contain virtually no 'red cell' ADA. The final pattern resembles that seen in kidney extracts. These changes are presumably due to the removal of negatively charged sialic residues from the tissue ADA *a*, *b* and *c* isozymes. The *d*₁ and *d*₂ isozymes were not affected by treatment with neuraminidase and this is most easily demonstrated using extracts of kidney (Fig. 1). The 'red cell' ADA and the *e* isozyme were also not affected by the neuraminidase treatment.

The ADA isozymes in liver, kidney, intestine and various other tissues were investigated by affinity chromatography on concanavalin A-Sepharose and wheat germ lectin-Sepharose. Concanavalin A is known to bind to glycoproteins containing terminal α -D-mannopyranosyl and α -D-glucopyranosyl residues and internal 2-O-D-mannopyranosyl groups^{10,11}. Wheat germ lectin binds *N*-acetylglucosamine residues specifically and sialic acid residues nonspecifically¹².

'Red cell' ADA and the tissue *e* isozyme failed to bind to either lectin, but the other tissue isozymes showed affinity for one or both lectins. Isozyme *a* was adsorbed by both lectins. The relatively weakly active isozymes *b* and *c* seemed to be adsorbed to concanavalin A but their affinity towards wheat germ lectin was not thoroughly investigated. The *d* isozyme showed heterogeneity in its adsorption characteristics. Re-chromatography experiments showed that this was not due to overloading. In the kidney the more cathodal component (*d*₂) was adsorbed by both lectins whereas the more anodal component (*d*₁) was only partly adsorbed. In the liver and intestine where the major component of the *d* isozyme has the mobility of *d*₁, contrasting results were obtained with wheat germ lectin and concanavalin A. The *d*₁ isozyme was mostly adsorbed by concanavalin A but not by wheat germ lectin (Fig. 2).

Lectin affinity chromatography was also conducted using neuraminidase treated liver extracts since the removal of sialic acid residues might alter the affinity characteristics of the isozymes. The affinity of the isozymes towards concanavalin A was unaffected by neuraminidase treatment, but the results of the experiments using wheat germ lectin were hard to interpret and two-stage experiments were therefore conducted. Untreated liver extracts were first of all fractionated by chromatography on wheat germ lectin-Sepharose. Both the fractions were then treated with neuraminidase. The nonadsorbed *d*₁ isozyme was not affected by this treatment. The adsorbed *a* isozyme was converted into the two forms of the *d* isozyme, *d*₁ and *d*₂ (Fig. 2). This material was then re-chromatographed on wheat germ lectin. The *d* isozyme was largely not adsorbed whereas the *d*₂ isozyme was adsorbed. Thus, it seems that the *a* isozyme exists in at least two forms with overlapping electrophoretic mobilities: one *a*₂ which may contain

Fig. 1 Effect of neuraminidase treatment on the ADA isozyme pattern of red cell, liver and kidney extracts. *A*, Photograph of a starch gel and *B*, a diagrammatic representation of the isozymes. Open rectangles represent the 'tissue' ADA isozymes. Shaded rectangles represent the 'red cell' ADA isozymes. On the gel shown the *d*₁ and *d*₂ isozymes were not clearly resolved, but are illustrated as two isozymes in the diagram. Neuraminidase treatment was performed by incubating 50 μ l of aqueous tissue extract with 20 μ l of neuraminidase solution (from *Clostridium perfringens*, Sigma type VI; 1 unit per ml, in 10 mM phosphate citrate buffer pH 5.0) for 2 h. [Similar results were also obtained using *Vibrio cholerae* neuraminidase.] Electrophoresis and detection were done as described by Edwards *et al.*³.

Fig. 2 Affinity chromatography of liver extracts using wheat germ lectin-Sepharose. **A**, Photograph and **B**, diagrammatic representation. 1, Unfractionated control; 2, material that was not adsorbed; 3, material that was adsorbed and subsequently eluted with 10^{-4} M N -acetylglucosamine; 4, sample 3 treated with neuraminidase. The chromatography was conducted using Wheat germ lectin-Sepharose 6MB (Pharmacia) or wheat germ lectin-Sepharose synthesised using Sepharose 4B CNBr-activated (Pharmacia) and wheat germ lectin (Sigma), at 25 °C using a column bed volume of 3 ml and a sample size of up to 0.5 ml crude aqueous tissue extract (1:1 weight to volume). Equilibration and elution of unadsorbed proteins was conducted using a 0.05 M phosphate buffer, pH 7.0, containing 0.2 M NaCl. Elution of adsorbed material was performed using this same buffer containing 10^{-4} M N -acetylglucosamine. These two fractions were concentrated and dialysed before electrophoresis. (The methodology used for concanavalin A-Sepharose affinity chromatography was similar, but in this case the buffers were 0.1 M acetate pH 6.0 containing 1 M NaCl, 1 mM $MgCl_2$, 1 mM $MnCl_2$ and the same buffer containing 20^{-4} M methyl α -mannopyranoside for elution.)

appropriately linked N -acetylglucosamine residues and is converted into the d_2 isozyme, and the other, a_1 , without the appropriate N -acetylglucosamine, which is converted into d_1 . Both forms apparently contain sialic acid which is accessible to neuraminidase.

Further experiments using two-stage chromatographic separations involving both wheat germ lectin and concanavalin A indicate that there are several forms of the d isozyme in human tissues: d_{1a} with affinity for concanavalin A, but not wheat germ lectin; d_{1b} with affinity for neither lectin and d_{1c} and d_2 with affinity for both lectins. These isozymes occur in varying amounts in different tissues. It therefore seems likely that the so-called a , b , c and d isozymes each represent a multiplicity of forms with overlapping electrophoretic mobilities which differ only in their carbohydrate side chains.

The tissue ADA e isozyme does not fit readily into this scheme—our evidence suggests that it may not be a glycoprotein. It is also unusual in its restricted tissue distribution, occurring only in large amounts in the intestine, and its much larger apparent molecular size (435,000) (ref. 3) than the other tissue isozymes (230–280,000) (refs 3,5). It is possible that another protein converting factor is involved in the generation of the e isozyme from red cell ADA or the e isozyme may be coded by a separate structural locus. An alternative and perhaps simpler explanation is that the (glyco) protein which leads to the conversion of red cell ADA into the a , b , c and d isozymes is also responsible for the generation of the tissue ADA e isozyme, but the composition of the sugar chains may be different.

Translation of human immunoglobulin heavy chain mRNA *in vitro*

MOUSE immunoglobulin (Ig) mRNAs have been the subject of intensive study. Purification of Ig light chain mRNAs from myeloma or plasmacytoma cells has been monitored by translation *in vitro*, and studies have been directed towards sequence determination and gene titration. Moreover, partial purification of Ig heavy chain mRNA has also been achieved^{1–3}. No comparable work on the Ig mRNA of any other species has yet been published. We report here the preparation, fractionation and translation *in vitro* of mRNA from cells of a cloned normal human B lymphocytic cell line, RPMI 1788 (ref. 6), grown in tissue culture. Human Ig μ chains were identified in the translation product by specific immunoprecipitation and electrophoretic mobility in sodium dodecyl sulphate (SDS)-urea polyacrylamide gels.

Preliminary experiments were carried out on a range of human lymphocytic cell lines supplied by Searle Research Laboratories, High Wycombe, and RPMI 1788 was chosen for this work because it produced the highest level of Ig (5%–10% of total protein synthesis) in tissue culture. All of this Ig synthesis in RPMI 1788 is of the IgM type, that is, μ heavy chains and λ light chains. Analysis of the Ig production *in vivo* is shown in Fig. 1. The feasibility of using this cell line for the preparation of Ig mRNA was further indicated by the observation that the rate of protein synthesis and the level of IgM production are maintained when cells are grown in medium containing swine serum rather than the more costly foetal calf serum, and also when the cells are grown to a high density (up to 8×10^5 cells per ml) in suspension culture.

Total RNA was prepared from about 5 g wet weight

RPMI 1788 cells, freshly collected, essentially following the method of Bedard and Huang¹. The total yield of 6 mg RNA was fractionated in sucrose gradients into a high molecular weight (HMW) fraction (5.5 mg) and a low molecular weight (LMW) fraction (0.5 mg) as shown in Fig. 2. The RNA in each of these pools was passed through

Fig. 1 Polyacrylamide gel electrophoresis identifying Ig chains synthesised by RPMI *in vivo*. RPMI 1788 cells (10^7) suspended in 2 ml RPMI 1640 medium containing 250 μ Ci 3 H-leucine were incubated at 37 °C for 6 h, collected and lysed in 1 ml lysis buffer containing 0.5% Nonidet P40, according to the method of Prekumar *et al.*^{7,8}. Antibody precipitations were performed on 0.5 ml aliquots of the cell lysate and on 1 ml aliquots of the labelled medium as follows: 6 μ l rabbit antiserum to human μ -chain or to bovine serum albumin (Miles) were added and the samples incubated on ice 45 min before the addition of 15 μ l goat anti-rabbit IgG antiserum (Miles). Samples were incubated a further 45 min on ice and the immunoprecipitates were then collected, washed three times with phosphate buffered saline and once with ethanol-ether (1:1) containing 1% β -mercapto-ethanol, dried in a vacuum, and then dissolved and reduced by the addition of 50 μ l 6 M urea, 10 mM sodium phosphate, pH 7.5, 2% sodium dodecylsulphate (SDS), 1% β -mercapto-ethanol, 10% sucrose and incubation at 90 °C for 2 min. Each sample was electrophoresed in 10% polyacrylamide disc gels (6 mm \times 6 cm) containing 6 M urea, 0.1 M sodium phosphate, pH 7.5, and 0.4% SDS, for 16 h at 2.5 mA per gel with a reservoir buffer of 0.1 M sodium phosphate, pH 7.5, 0.1% SDS and 5 mM thioglycolic acid. Gels were frozen and sliced at 1 mm intervals and each slice was incubated in 0.3 ml Soluene 350 (Packard) and the radioactivity monitored in toluene scintillant. Panels show anti- μ -chain immunoprecipitates of the cell lysate (a), and of the medium (b). Unlabelled human μ , γ , and λ chains were run in a parallel gel and their positions at the end of electrophoresis are indicated. A similar gel of the anti-bovine serum albumin immunoprecipitate (not shown) revealed no μ or λ chains.

Fig. 2 Sucrose gradient fractionation of RPMI 1788 microsomal RNA. Microsomal RNA was prepared and sedimented through sucrose gradients using the method of Bedard and Huang². All manipulations were at 4 °C unless otherwise indicated. The cells were homogenised by six strokes in a tight fitting glass-Teflon homogeniser in 5 volumes of 4 mM Tris (pH 7.4), 1.5 mM $MgCl_2$, 25 mM KCl, 250 mM sucrose. Nuclei and cell debris were pelleted at 3,000g for 10 min and the supernatant was removed and centrifuged at 30,000 r.p.m. (100,000g) for 20 min in a Beckman SW 41 rotor. The resultant microsomal pellet was dissolved in 2 volumes 5 mM Tris buffer, 3% SDS, at room temperature and immediately extracted twice on ice with 1 volume of phenol and subsequently 1 volume chloroform. The RNA was precipitated from the aqueous phase by addition of ethanol, washed, dissolved in water and layered on four 5%–30% sucrose gradients made in 0.1 M NaCl, 10 mM Tris (pH 7.5), 1 mM EDTA, 0.5% SDS. Gradients were centrifuged at 25,000 r.p.m. in a Beckman SW 41 rotor at 25 °C for 16 h, and then were fractionated by displacement from the bottom with 40% sucrose, while the fractionation was monitored with an Isco UA-4 (see trace). The fractions were pooled as indicated and the RNA in each pool was collected by ethanol precipitation, washed, and purified on oligo dT-cellulose (T-3; Collaborative Research) at room temperature in the presence of 10 mM Tris buffer and 0.5% SDS. The poly-A⁺ RNA, as well as the poly-A⁻ RNA, from each gradient were collected and washed as above, re-dissolved in water and stored at -20 °C.

a column of oligo dT-cellulose to separate the polyadenylated (poly-A⁺) RNA, presumably mRNA, from the non-polyadenylated (poly-A⁻) RNA. The HMW pool of Fig. 2 yielded 80 μ g poly-A⁺ and 2.1 mg poly-A⁻ RNA; the LMW pool yielded 18 μ g poly-A⁺ and 330 μ g poly-A⁻ RNA.

Three of these RNA fractions were analysed in 250 μ l rabbit reticulocyte lysates for their ability to stimulate protein synthesis *in vitro*. HMW poly-A⁺ RNA (25 μ g), LMW poly-A⁺ RNA (15 μ g), and HMW poly-A⁻ RNA (50 μ g), added to the assay system stimulated the incorporation of labelled amino acid to levels of 5,470, 3,031, and 708 c.p.m. above background (background=1,291 c.p.m.) per 2 μ l aliquot. Each of the incubated lysates was precipitated with antiserum to human μ chain. Only the HMW poly-A⁺ RNA stimulated lysate contained specifically immuno-

(Miles). After incubation at 37 °C, for 90 min each sample was layered over a discontinuous sucrose gradient (100 μ l 1 M sucrose + 50 μ l 0.5 M sucrose) in a 400 μ l Beckman microfuge tube and centrifuged at 16,000g for 5 min. The tubes were frozen at -80 °C and the tip of each was cut off in order to collect the antibody precipitates, which were then dissolved, reduced, monitored for radioactivity and electrophoresed in 10% polyacrylamide disc gels as described in the legend to Fig. 1. The gel patterns shown represent the anti- μ -chain immunoprecipitates obtained from lysates containing 60 μ g ml⁻¹ LMW poly-A⁺ RNA (a), 200 μ g ml⁻¹ HMW poly-A⁺ RNA (b), and 100 μ g ml⁻¹ HMW poly-A⁺ RNA (c). The gel pattern (not shown) of the anti-ovalbumin immunoprecipitate from a lysate containing 100 μ g ml⁻¹ HMW poly-A⁺ RNA is identical to patterns (a) and (b). The gel pattern (not shown) of the anti-ovalbumin immunoprecipitate from a lysate containing 200 μ g ml⁻¹ oviduct polysomal RNA shows one labelled peak well separated from the μ -chain position and co-migrating with the unlabelled ovalbumin marker.

Fig. 3 Polyacrylamide gel electrophoresis demonstrating Ig μ -chain mRNA from human lymphocytes translated *in vitro*. RNA samples were analysed in 250 μ l rabbit reticulocyte lysates prepared by the method of Palmiter⁹, but buffered with 14 mM HEPES, pH 7.6, stored at -80 °C, and pretreated with micrococcal nuclease by the methods of Pelham and Jackson¹⁰. After addition of 22 μ Ci ³⁵S-methionine and the RNA to be tested, each lysate was incubated for 90 min at 26 °C. Aliquots of 2 μ l were precipitated with trichloroacetic acid and precipitates were washed, dried and monitored for radioactivity as a measure of total protein synthesis. To determine the quantity of μ chain synthesised, the remainder of each 250- μ l lysate was immunoprecipitated as follows: lysates were each mixed with 50 μ l 50 mM methionine, 25 μ l 10% Triton X-100, 25 μ l 10% sodium deoxycholate, and 4 μ l human IgM (8.7 mg ml⁻¹) or, as a control, 9 μ l ovalbumin (1 mg ml⁻¹) and centrifuged at 16,000g for 5 min. From each sample the top 225 μ l was removed and added to 50 μ l anti-human μ -chain antiserum (Miles) or 50 μ l anti-ovalbumin antiserum

precipitable protein. The amount of radioactivity recovered in the immunoprecipitate (multiplied by 3 since only one-third of the HMW poly-A⁺ RNA was tested in the assay) equals 0.7% of the total protein synthesised in response to the three RNA fractions (obtained as the sum of the correspondingly normalised activities). Gel electrophoresis of the immunoprecipitates in Fig. 3 shows that the protein precipitated by the μ -chain antiserum is homogeneous, and identical in mobility to human μ -chain marker. These results indicate the presence of intact, translatable μ -chain mRNA in the HMW poly-A⁺ fraction of RNA prepared from human lymphocytes.

The cells used in the experiments described above were freshly collected, but this does not seem to be essential. The entire procedure has been repeated using a similar quantity of cells which had been rapidly frozen in liquid N₂ as a cell pellet and stored at -80 °C before RNA preparation. The results of the second experiment, including yields of RNA, the sedimentation pattern of the RNA, the yields of poly-A⁺ and poly-A⁻ RNA and the ability of the HMW poly-A⁺ fraction to stimulate the *in vitro* synthesis of anti- μ chain precipitable protein, were essentially identical to the results with freshly collected cells illustrated in Figs 2 and 3. The second preparation yielded a percentage of anti- μ -chain precipitable protein of 3.4%, which approaches the level of 5%–10% estimated for *in vivo* synthesis.

In this second experiment, the 18S peak from the sucrose gradient was pooled separately from the rest of the HMW fraction. Immunoprecipitation of the *in vitro* translation products showed that more than 90% of the μ -chain mRNA is located in the 18S fraction, indicating that this mRNA has a sedimentation coefficient of around 18S. This result may be compared with reports that, in mouse, the α -heavy chain mRNA (from MOPC 315 plasmacytoma) sediments at

16–19S (ref. 3), and γ -chain mRNA (from MOPC 21 tissue culture cells) at 17S (ref. 1), and suggests that the human μ -heavy chain mRNA may be of similar size. Work is now in progress to prepare large quantities of RPMI 1788 RNA to be used for the further physical and chemical characterisation of the Ig mRNA.

We thank Dr Brian Richards, Dr John Birch and Mr David Edwards of Searle Research Laboratories for support and collaboration, Dr Ru Chih Huang for advice, and Mr Paul Singer for help with preliminary experiments. This work was supported by MRC grant G969/509/B, USNIH postdoctoral fellowship 1-F32 GM 05558-01 (C.K.K.), and a King's College tutorial fellowship (F.C.).

Identification of chromosomal location of yeast DNA from hybrid plasmid *pYeleu10*

THERE is strong evidence to suggest that some genes of baker's yeast *Saccharomyces cerevisiae* can be expressed in *Escherichia coli* when cloned on plasmid or phage vectors^{1,2}. This conclusion is based on the observation that hybrid plasmids and bacteriophage carrying specific fragments of yeast nuclear DNA can complement certain auxotrophic mutations in the *E. coli* genome. Complementation alone, however, is not sufficient to prove that the cloned DNA contains a yeast gene equivalent to the defective bacterial gene. One aspect of the identification of any cloned DNA is the identification of its chromosomal origin. We present here a method for the identification of the chromosomal origin of cloned yeast DNA using hybridisation to DNA from yeast strains aneuploid for a single chromosome. Using this method we have confirmed the chromosomal location of the DNA of a yeast hybrid plasmid (*pYeleu10*) presumed to contain sequences coding for the leucine biosynthetic enzyme β -isopropylmalate dehydrogenase, the *leu2* gene of yeast.

Ratzkin and Carbon¹ attempted to isolate a hybrid plasmid containing a functional yeast *leu2* gene by transformation of a *leu*⁻ bacterial strain (JA199; *leuB6*, *trpE5*, *lacY*⁻ *hsdR*⁻ *hsdM*⁻/*F*⁺) defective in β -isopropylmalate dehydrogenase to *leu*⁺ using randomly sheared yeast DNA cloned on the plasmid vector *ColE1*. These workers isolated several independent clones which contained plasmids capable of suppressing the *leuB*⁻ defect in the host cell. Analysis of the restriction patterns of the plasmid DNA from these clones gave the surprising result that at least four distinct yeast DNA sequences were represented among these plasmids. As only one locus (*leu2*) is known in yeast to code for the enzyme β -isopropylmalate dehydrogenase, this result meant that in at least some cases suppression of the host

leuB mutation could occur by means other than enzymatic complementation. This result emphasises that complementation does not provide clear evidence for the presence of a specific functional gene or a unique segment of DNA corresponding to the yeast *leu2* region. Further genetic tests by these workers showed that one plasmid, *pYeleu10*, complemented several *leuB*⁻ alleles while the rest were specific for the original allele, *leuB6*. For this reason it seemed likely that plasmid *pYeleu10* might be expressing the cognate yeast gene, *leu2*, which is located on the left arm of chromosome III, near the centromere.

To determine unambiguously the chromosomal location of the yeast DNA carried by *pYeleu10*, we have analysed the hybridisation of labelled plasmid DNA to yeast DNA from strains aneuploid for chromosome III. Hybridisation was carried out after transferring restriction digests of the yeast DNA to nitrocellulose filters by the Southern blotting procedure³. The rationale for the experiment was that in the conditions used (that is, excess probe) the amount of label bound should be directly related to the amount of DNA originally present on the filter, and therefore that the degree of hybridisation to bands from chromosome III should reflect the aneuploid condition. The yeast strains used are described in Table 1 and include a normal haploid, a normal diploid, a diploid monosomic for chromosome III ($2n-1$) and a haploid disomic for chromosome III ($n+1$). Thus, the amount of chromosome III DNA per haploid genome (n) in each strain varied from $n/2$ (H151-2A) to n (+D4, 8481) to $2n$ (H159/1). It should be emphasised that the success of this and similar experiments depends on an accurate determination of the genotype of the aneuploid strains at the time of DNA isolation. Aneuploidy in most organisms, including yeast, is an unstable condition and strains may frequently revert to euploidy during culture. Genetic assays for aneuploidy in strains H159/1 and H151-2A are described in the legend to Table 1. Methods used for isolation and labelling of DNA along with conditions for hybridisation are described in the legend to Fig. 1. The hybridisation probe consisted of a mixture of ³²P-labelled

Table 1 Yeast strains used

Strain	Chromosome no.	Genotype	Copies of chromosome III per haploid genome
A364a + D4	$2n$	<i>ura1 ade1 ade2 a</i> <i>ura1 ade1 ade2 a</i>	1
8481	n	<i>his4-260 a HOL1-1</i>	1
H159/1	$n+1$	<i>his4-38 leu2-1_{oc} a</i> + <i>lys1-1_{oc} can1-100_{oc} met8-1</i> <i>his4-280 leu2-1_{oc} a SUP61</i>	2
H151-2A	$2n-1$	<i>his4⁻ leu2-1 a thr4 mal2</i> <i>lys1-1 ade2-1</i> + +	$\frac{1}{2}$
S36	$2n-1$	<i>a ino1-13 ino4-8</i> <i>ino1-13 ino4-8</i>	$\frac{1}{2}$

Strains were constructed in this laboratory by standard genetic techniques⁶ with the exception of A364a + D5 which was obtained from Lee Hartwell. The media used were described previously⁷. Cultures of H159/1 and H151-2A used for preparation of yeast DNA were tested for aneuploidy immediately before collecting as follows. H151/1: the culture was diluted and plated on YEPD (complete) agar for single colonies and tested for expression of genetic markers by replica plating. Because of the presence of the ochre suppressors *SUP61* (Hawthorne, personal communication) the phenotype of a colony arising from an aneuploid cell of the genotype shown in this Table will be *Leu*⁺ *Lys*⁺ *His*⁻ *Met*⁻ *canavanine* sensitive (*Can*^s) and non-mating (*a/a*). But, because of the spontaneous loss of the chromosome containing the suppressor, some cells in the colony exhibit an altered phenotype, *Leu*⁻ *Lys*⁻ *His*⁻ *Met*⁻ *Can*^r and mating type *a*. Such segregants can be detected by plating on medium containing canavanine and subsequently testing the *Can*^r segregants for the other nutritional markers and mating type. The presence of these segregants in a clone provides evidence that the parent cell was aneuploid. All 289 colonies tested exhibited all aspects of this complex phenotype and the culture was assumed to contain virtually 100% aneuploid ($n+1$) cells. H151-2A: an aliquot of this culture was mated with cells of strain S36 on YEPD agar, then transferred to SPOR agar to induce meiosis and sporulation. Tetrads were dissected and assayed for each of the genetic markers in the cross. Because the two strains were mated *en masse*, resulting in the formation of thousands of independent zygotes, it was assumed that each tetrad was the result of an independent mating event and thus reflected the genotype of an individual cell from the H151-2A culture. Tetrads resulting from matings involving aneuploid H151-2A cells would be expected to exhibit 2:2 segregation for each of the alleles located on chromosome III. But, tetrads exhibiting 4:0 or 3:1 segregation for mating type, cryptopleurine resistance (*Cry*^r) or maltose fermentation would indicate that two copies of each of these alleles were present and that parent H151-2A cell had reverted to euploidy. Of 83 tetrads, 70 scored were of the former type (2:2) indicating that the culture of H151-2A from which DNA was isolated contained at least 80% aneuploid ($2n-1$) cells. *Lys1-1* and *ade2-1* exhibited normal tetraploid segregation.

DNA from *pYeleu10* and *YPH-1*, a hybrid plasmid created in this laboratory containing an unidentified segment of yeast DNA. *YPH-1* was used as an internal standard for the extent of hybridisation. Although its chromosomal location is not known, it is presumed not to be located on chromosome III because hybridisation of *YPH-1* to whole yeast DNA is not affected by aneuploidy of chromosome III (J.H., unpublished). *Hind* III was used to digest the yeast DNA because neither *pYeleu10* nor *YPH-1* are cut by this enzyme and each should thus be represented by a single band in a yeast *Hind* III digest.

The results of one hybridisation experiment are shown in Fig. 1. The degree of hybridisation in each of the two main bands was assayed by cutting out and weighing the two main peaks in the densitometric tracings. As shown in Table 2, the ratio of the peak areas in each track varies

directly with the ratios of chromosome III per haploid genome. This result was confirmed by cutting the bands out of the filter and assaying radioactivity in a scintillation counter (not shown). From these data we conclude that *pYeleu10* carries sequences located on chromosome III. This experiment has been repeated with similar results (not shown).

An intriguing feature of the radioautograph obtained by this procedure is that faint bands are observed in each track in addition to the single main band associated with each plasmid. These are present even when *pYeleu10* alone is used as probe and have been frequently observed by other workers (K. Struhl and J. Carbon, personal communication). It is not likely that they are the result of incomplete digestion of the yeast DNA since some of them are smaller than the smallest *Hind* III fragment which could correspond to *pYeleu10*, that is, a fragment equal in size to *pYeleu10* itself since *pYeleu10* contains no *Hind* III restriction sites. It is tempting to speculate that these 'ghost bands' might represent partially homologous sequences scattered throughout the genome which have a common regulatory or structural function.

We conclude that plasmid *pYeleu10* contains sequences from chromosome III of yeast, probably including the *leu2* locus. Using this plasmid as a probe it will be possible to locate sequences flanking the *leu2* region among collections of clones containing yeast DNA and by repeating that process to 'walk' down the chromosome to other regions of

Fig. 1 *a*, Radioautograph of ^{32}P -labelled DNA from plasmids *pYeleu10* and *YPH-1* hybridised to a 'Southern blot' (ref. 3) containing *Hind* III restriction digests of yeast DNA. *b*, Densitometer tracings of the individual tracks in the radioautograph. Yeast DNA was prepared by the method of Cryer, Eccleshall and Marmur⁸. Approximately 2 μg of DNA from each strain was digested with restriction endonuclease *Hind* III (New England Biolabs; 2 units per μg DNA, 37 °C for 4 h) and subjected to electrophoresis on a horizontal 0.8% agarose slab gel (1.3 \times 15 cm tracks) for 12 h at 4 mA per track. The restriction digest in the gel was then transferred to a nitrocellulose filter (Millipore HAWP) by the Southern blotting procedure⁹. DNA from plasmids *pYeleu10* and *YPH-1* was isolated by a modification of procedures described by Clewell⁹ and Guerry *et al.*¹⁰. Cultures were grown in supplemented synthetic medium to mid-log phase ($2\text{--}4 \times 10^8$ cells per ml) at which time chloramphenicol was added to a concentration of 250 mg l^{-1} and the cultures were shaken at 37 °C for 25 h to allow amplification of the plasmid⁹. The culture was divided into 200-ml aliquots for further processing. Cells were collected by centrifugation, washed in 10 mM Tris-1 mM EDTA, pH 8.0 and resuspended in 2 ml 50 mM Tris-25% sucrose, pH 8.0 plus 2 mg lysozyme (Worthington). The mixture was incubated 5 min at 0 °C before addition of 0.4 ml EDTA, pH 8.0 and further incubation for 10 min at 0 °C. Lysing buffer (1% Triton X-100, 1 mM EDTA, 50 mM Tris, pH 8.0) 4 ml was added followed by incubation for an additional 15 min at 0 °C. The lysate was then centrifuged for 90 min at 18,000 r.p.m. in a Sorvall SS-34 rotor to pellet cell debris and most of the chromosomal DNA. The supernatant was then carefully decanted away from the loose pellet, volume was adjusted to 8.0 ml with 0.5 M EDTA and 0.3 ml ethidium bromide (10 mg ml^{-1}) was added. Protein precipitated by the CsCl-EtBr was removed by centrifugation at 30,000g and the cleared supernatant centrifuged for 40 h at 40,000 r.p.m. in a Beckman 65 rotor. The plasmid DNA band was extracted from the density gradient as described by Clewell⁹. Ethidium bromide was removed by three extractions with isopentyl alcohol followed by dialysis against 10 mM Tris-1 mM EDTA pH 7.5. Plasmid DNA was labelled with ^{32}P by nick translation using DNA polymerase I (Boehringer-Mannheim Grade I) according to the method of Maniatis *et al.*¹¹. Specific activity of the labelled plasmid DNA was 1.1×10^6 Ci μg^{-1} . After denaturation of the probe DNA in 0.2 M NaOH at 65 °C, hybridisation to the filter-bound DNA was accomplished in 10 ml of $4 \times \text{SSC} + 0.1\%$ sodium dodecylsulphate at 65 °C for 44 h. The filter was then exhaustively washed in 3 mM Tris base (M. Botchan, personal communication) and exposed to Kodak No-Screen X-ray film (NS2T) for 3h. The exposed film was then scanned using a densitometer. The sensitivity of the densitometer was adjusted for each scan to normalise approximately *YPH-1* peaks.

Table 2 Comparison of the peak areas in the densitometric tracings in Fig. 1

Strain	Weight of cut-out peak (mg) <i>pYeleu10</i>	Weight of cut-out peak (mg) <i>YPH-1</i>	Ratio: <i>pYeleu10</i> / <i>YPH-1</i>	Copies of chromosome III per haploid genome
H151-2A	17.1	10.2	1.4	$\frac{1}{2}$
8481	36.7	11.7	3.1	1
+D4	32.7	10.2	3.3	1
H159/1	66.8	11.6	5.8	2

Areas were measured by reproducing the densitometer tracings onto heavy paper, cutting out two copies of each peak (as indicated by the dotted lines) and weighing each one. Weights shown are the average of two measurements.

interest. It should further be possible to identify cloned DNA from specific genetic loci by hybridisation to restriction digests of DNA from yeast strains carrying genetically defined deletions which enter these loci. Southern blots of DNA from such strains should exhibit altered hybridisation patterns relative to wildtype DNA. Deletions exist which have endpoints in or near the *his4* locus⁴, the centromere (H. Klein and G. F., unpublished), and the mating type locus⁵. Attempts to isolate the DNA from these loci by this approach are under way.

We thank Barry Ratzkin and John Carbon for allowing us to use the *pYeleu10* plasmid and Dick Hallberg for informative discussion. This work was supported by NIH grant GM15408 (G.R.F.) and an NIH Post-doctoral Service Award (J.B.H.). All work involving living cells containing recombinant DNA was performed in accordance with the NIH Guidelines for Recombinant DNA Research¹².

Deuterium NMR study of lipid organisation in *Acholeplasma laidlawii* membranes

THE most convincing studies of molecular order in model membranes are undoubtedly those involving deuterium nuclear magnetic resonance (NMR) of labelled lipids in the lamellar liquid crystalline phase¹⁻⁶. The relevance of these results to biological membranes has not yet been established, however; there is no *a priori* reason to expect the state of organisation of lipids in the lamellar liquid crystal to resemble closely that of a natural membrane. We report here the first detailed study of acyl chain order in the lipids of a natural biological membrane—the plasma membrane of the microorganism *Acholeplasma laidlawii*. Specifically deuterated fatty acids were incorporated biosynthetically into the membrane lipids as described previously⁷. The ²H-NMR spectra of the membrane demonstrate the co-existence of at least two different kinds of lipid. Signals

Fig. 1 ²H-NMR spectra, at 13.8 MHz, of *Acholeplasma laidlawii* membranes containing palmitate-13d₂. At 42 °C (a) the spectrum is dominated by the fluid phase with the splitting indicated by the two arrows. As the temperature is lowered (b, 30 °C; c, 25 °C), the spectrum appears more characteristic of a gel. All the spectra were recorded at a repetition rate of 4 scans per s. The number of scans was 120,000 at 42 °C and 40,000 at 30 °C and 25 °C. The spectra were symmetrised about the Larmor frequency which is represented by zero.

from the more fluid lipid are most prominent at temperatures near and above the growth temperature (37 °C). The more solid-like lipid, which predominates at lower temperatures, may be similar to the gel state of lamellar phases and could include lipid associated with the membrane protein. For the more fluid phase, the plot of order parameter against position of deuteration strongly resembles that for egg yolk² and dipalmitoyl³ phosphatidylcholine. Incorporation of cholesterol into the membrane of *A. laidlawii* increases the average acyl chain order and also increases the spread of order parameters, similar to its effect on egg yolk phosphatidylcholine⁸. These results represent a major justification for the use of lamellar liquid crystals as models for the lipid in biological membranes.

The NMR samples consisted of 0.5–1.3 g of lyophilised *A. laidlawii* membranes which were hydrated with 1–3 ml of distilled water. The average acyl chain composition of the membrane lipids was as follows: 12:0 = 6.6% (1.2); 14:0 =

Fig. 2 The distance between the peaks in the powder pattern, $\Delta\nu$, against position of deuteration of the palmitate chains at 42 °C. Points connected by dotted lines were obtained from samples labelled in two adjacent positions for which the two powder patterns are not resolved. Error bars are estimated from the spectra and do not include possible effects due to variation in membrane composition.

18.1% (2.3); 16:0 = 68.8% (3.6); minor components = about 6.5% as determined by gas-liquid chromatography. The values given represent mean compositions for all 10 specifically labelled samples. The numbers in parentheses are average deviations from the mean. Thus the membrane lipid chains were enriched to about 70% with specifically deuterated palmitate. The small random variation in chain composition, which seems to be unavoidable in this experiment, is independent of the position of deuteration in the palmitate chain.

The ^1H -NMR spectra of labelled biological membranes are characterised by quadrupolar 'powder' spectra spanning a wide frequency range and with residual quadrupolar splittings of 10^4 – 10^5 Hz (refs 2, 7). A quadrupolar spin echo technique ('solid echo') was used here to obtain undistorted spectra. The merits of this simple pulse technique, necessary to these experiments, have been discussed in detail by Davis *et al.*⁸. The signals were recorded at the ^1H Larmor frequency so that the low field half of the symmetrical quadrupolar powder spectrum appears folded and superimposed on the high field half, thus increasing the detection sensitivity by a factor of $\sqrt{2}$. To facilitate visual interpretation of these spectra, we plotted sample spectra reflected about the symmetry axis to simulate the appearance of a complete spectrum and show the quadrupolar splitting (Fig. 1). The reader should not be misled by the apparent perfect symmetry of these spectra.

As shown in Fig. 1, above the growth temperature of 37 °C, the ^1H -NMR spectra are dominated by a quadrupolar powder spectrum which resembles strongly those observed for simple liquid crystalline phospholipids^{2,3}. At lower temperatures, signals characteristic of a more solid-like phase appear. This behaviour is entirely consistent with the extremely broad thermal phase transition reported previously for *A. laidlawii* membranes derived from palmitate-supplemented media⁹. The quadrupolar splittings and related order parameters S_{CD} were measured as a function of the position of the deuterium label in the palmitate chain for the fluid phase of *A. laidlawii* membranes at 42 °C. A plot of the deduced order parameters S_{CD} against position of deuteration is shown in Fig. 2. This plot has the same characteristic shape as those found for lamellar liquid crystalline phases of single phospholipids^{2,3}. The 'plateau' region of constant order extends from carbon

2 to at least carbon 8 as for the lamellar phases, and the actual values for S_{CD} are comparable with those found for egg yolk and dipalmitoyl phosphatidylcholine^{2,3}. The important consequence of these findings is that inferences concerning acyl chain conformation and bilayer geometry, and their relationship to biological function, made previously for the lamellar phases^{2,3} apply also to *A. laidlawii* membranes.

The spectrum for membranes containing 2,2-dideuterio-palmitate is considerably different from that for any other label position. The unusual shape of the line suggests the presence of possibly three overlapping powder doublets. The quadrupolar splitting for this position is expected to be very sensitive to differences in the initial conformation of the two acyl chains¹⁰, and also to differences in the head groups (*A. laidlawii* lipids contain several different head groups).

The effect of incorporation of cholesterol into *A. laidlawii* membranes was investigated using fully deuterated palmitate chains. While this technique was highly successful in probing the effect of cholesterol on egg yolk phosphatidylcholine⁸, much less resolution of the NMR signals for individual chain positions was obtained for the membranes (see Fig. 3). Nevertheless, the general shape of the envelope due to numerous overlapping powder doublets can provide useful information⁸. The sharp edges of the envelope are characteristic of a system having a plateau region in the ordering profile¹¹ (Fig. 2). The effect of cholesterol is to spread the intensity of the NMR spectrum over a wider frequency range. This is consistent with the much greater ordering effect of cholesterol on the plateau region compared with the methyl end of the chain, as found previously for egg yolk phosphatidylcholine⁸. The increase in the quadrupole splitting from 30 to 50 kHz for the plateau region with 2:1 lipid:cholesterol ratio is very similar to that found for egg phosphatidylcholine⁸.

With the increased sensitivity of contemporary NMR techniques and the greater availability of deuterium-labelled lipids, ^1H -NMR provides an excellent method to probe the fine detail of molecular organisation in a biological membrane with a minimum of perturbation or approximation.

The research at UBC was supported by the National Research Council of Canada and by a special Killam-Canada Council Interdisciplinary Grant. J. H. D. is the holder of a NRC Postdoctoral Fellowship.

reviews

Energy crisis

John Chesshire

Energy: The Continuing Crisis. By Norman Metzger. Pp. 242. (Thomas Y. Crowell: New York, 1977.) \$12.95.

AS if to anticipate the reviewer, the author commences his study by questioning the need for yet another book on the "energy crisis". The justification lies in his belief that since 1973, energy consumers have been lulled into a dangerous complacency: new finds of fossil fuels are reported daily, and the nuclear and non-conventional technology lobbies sing in high praise of the potential of their systems. This appearance of plenty allows consumers the luxury of using yet more fuel while putting up stern and vocal criticism to planning applications for new nuclear stations, oil refineries and coal mines. Meanwhile, their elected representatives, whether in the US Congress or in the British House of Commons, point to the political implications of tough conservation measures, especially any which might bring about the transition of fuel prices to the long-term marginal costs of replacements. Thus, the "continuing crisis", and the need for another book.

The author adopts the now-common, fuel-by-fuel approach in his analysis, and focuses on the US situation. He points to the steady demise of coal this century, and to the massive injection of funds now required to raise production by providing new capacity and efficient mining, conversion and utilisation technologies. He concludes by arguing that the scale of the resource requirement is such that the vast expansion of the coal industry is by no means the certainty it seems to be in current energy policy planning.

Critical to his review of the oil sector is an analysis of the likelihood of continued cohesion of the OPEC cartel (a fixation with many American commentators). The absence of any discussion of the role of the state in determining alternative depletion policies is a weakness here, as in the succeeding chapter on natural gas. His useful arm's-length account of the "Troubled Youth of Nuclear Power" includes an assessment of recent American action and reaction in the build-up of nuclear generating capacity, and a damning indictment of the lack of attention to waste disposal

and storage, and leads him to the whimsical (but incisive) view that "maybe the trouble with nuclear reactors is that they don't have belching smokestacks".

Of the unconventional technologies, he anticipates that the major contribution will come from the fusion, solar and geothermal routes, and he highlights the critical uncertainties regarding the cost, scale and timing of their contribution to future energy supplies.

On balance, the author is to be commended for his realistic evaluation of the many exaggerated claims that have

been made about both fossil and novel energy supplies, and for his sensitive analysis of the constraints on change imposed by the power and vested interests of the energy corporations and the regulatory functions of the state. It is unfortunate that he favours a supply—rather than a demand—oriented approach, thus neglecting conservation policies and technologies and that he adopts a relatively short-term US-centred view of the world. □

Tracing the history of life

The Phylogeny of the Vertebrata. By Søren Løvtrup. Pp. xii+330. (Wiley: London and New York, 1977.) £15; \$29.50.

COMPARATIVE BIOLOGY has been revitalised in recent years under the stimulating influence of Willi Hennig's *Phylogenetic Systematics*. No longer can it be regarded as the feeble survivor of a primitive descriptive phase of biology, for it is evidently central to evolutionary biology and gives meaning and direction to research in fields as diverse as embryology, population genetics, biogeography and behaviour. It is based on a belief in the objective existence of a true path of descent for all living organisms which may be reconstructed by the empirical testing of well formed hypotheses. Nevertheless, despite its already long life, comparative biology is not yet a mature science with well understood philosophical and theoretical foundations. Søren Løvtrup's book attempts to remedy this defect, using the *Vertebrata* to exemplify his ideas.

The book opens by setting out its Popperian research programme and then immediately takes up the "Logic of Phylogenetics". By excluding fossils and thereby avoiding argument about what is in any case a practical rather than a theoretical difficulty, Løvtrup is able to treat classification and phylogeny reconstruction as the same process. Thus, of the two levels of taxonomic activity differentiated by Gregg—taxonomy proper and method-

ological taxonomy—Løvtrup attacks the latter. Taxonomy at the higher level is a primitive science. As Gregg says, "Taxonomists engaged in methodological research are [thus] without adequate linguistic resources to support their investigations. They must rely almost entirely upon unsuitable prescientific idioms borrowed from everyday language". Gregg's own solution was the use of set theory, but this had no hope of acceptance in a pre-Hennigian intellectual climate that deliberately depressed rigour and allowed artifice and authority to flourish. Twenty-five years later, Løvtrup is in a more favourable position, though it is perhaps unfortunate that his "language" is a series of definitions, axioms and theories, rather than the symbolic logic of Gregg.

The heart of Løvtrup's book comprises two long chapters on the ancestry and divergence of vertebrates. These are more easily approached than other chapters and will no doubt readily attract attention because of their heterodox conclusions. However, Løvtrup has more important things to say elsewhere in this book, and as he deviates so disastrously from his professed deductive approach, I am disinclined to give much weight to his conclusions. The last section of the book deals with the mechanism of evolution. Comparative biology has not benefitted greatly at a practical level from work in this field, and Løvtrup tries to redress the balance with an axiomatised version of his "comprehensive" theory. This is

distinguished by the importance it attaches to large step changes and the pressure of macromutations, over and above natural selection.

How well has Løvtrup succeeded in clarifying these important and difficult issues? Reluctantly, I must suggest that in large measure he has been unsuccessful, though whether this is due to the unsuitability of the methods adopted, or to the way these are used, is not a question that can be answered here. His arguments are based on formal language but are often illogical and imprecisely formulated. He purports to follow Popper but his theories are often unfalsifiable in principle or protected by phrases such as "Other things being equal". Large sections of the argument about relationships are indistinguishable from induction by enumeration and from the search for confirmation, as is shown by the repeated use of statements such as, "If we want to find support for the classification in Figure 4.12, we must look for characters in common between *Caudata* and *Salientia*".

The section which purports to confront his theory of vertebrate interrelationships with the facts of the fossil record, seems to rely heavily on the interpretation of the facts in the light of the theory they are said to support. Yet even this will not dispose of the Placodermi, which are therefore dismissed with an astonishingly vacuous quotation from Romer, which is said to seem "to be quite a close approximation to the truth". Unfortunately, the form of the argument is also imprecisely handled and this hinders comprehension. Some axioms are either self-contradictory or ambiguously stated, others are stated and then immediately refuted, and yet others introduced with an exception that is not defined until much later. At least one theory is a paraphrase of the definition from which it is said partly to be derived, and another is incompatible with the theory from which it is said to be deduced.

These are harsh criticisms of an honest attempt to deal in an explicit way with a number of difficult problems. I share Løvtrup's views on the importance of criticism and on the seriousness of the failure of many comparative biologists to make their assumptions, arguments and conclusions clear. Therefore, I recommend this book, particularly to those involved in tracing the history of life. For, despite its failures, it is full of challenging ideas, and I unreservedly commend the attitudes and hopes that motivated its writing.

Ellipsometry and polarised light

Ellipsometry and Polarized Light. By R. M. A. Azzam and N. M. Bashara. Pp. xvii+529. (North-Holland: New York, Amsterdam and Oxford, 1977.) Dfl.180; \$37.50.

ELLIPSOmetry is a technique for examining the optical properties of surfaces and thin films with polarised electromagnetic radiation. The technique is intrinsically very sensitive and deceptively simple in principle. Thus, it can readily be explained at a superficial level to students with only a minimal grasp of optics. Scientists who apply ellipsometry to investigate a wide range of phenomena, however, are aware of the need to take account of many possible sources of systematic error and of the consequent notorious difficulties in interpreting ellipsometric observations. The publication of a book of five hundred pages on ellipsometry will therefore not surprise them. Indeed, English-speaking scientists will welcome the first book of its kind written in their language by authors with international reputations for contributions to the development and use of ellipsometry.

The first two chapters are devoted to descriptions of well established and predominantly matrix methods of representing polarised radiation and the operation of optical elements with polarising properties. In chapter three the authors give an analysis of the main ellipsometric arrangements and a well ordered discussion of associated systematic errors; essentially the core

material of the book. The procedures for relating observable optical functions to the macroscopic optical constants of the materials of thin films and surfaces are presented in chapter four. Much of its contents can be found in other texts on thin film optics, but the account has been updated by references to recent work on anisotropic crystalline materials, as well as by a discussion of numerical inversion procedures. An account of instrumentation is given in chapter five with emphasis on imperfections and automation. In the final chapter, the authors provide a necessarily brief survey of the very wide range of physical surface investigation which has prompted the application of ellipsometry. Examples are taken from optics, physical chemistry, electrochemistry, particle radiation physics and biology.

The book is well written, with clear diagrams and few typographical errors. A pleasing feature of style are the separate introductions to each chapter, which provide the reader with a general preview of what is to follow. On the other hand, the balance of the material, which presumably reflects the authors' particular interests, will not be to the taste of some readers. For instance, the mathematical representations of polarised radiation are treated exhaustively at the expense of explanations of the underlying physical phenomena. A prominent example of inadequate emphasis concerns the ultimate sensitivity of ellipsometers; an important matter dismissed in a single paragraph.

Ethological dictionary

Ethological Dictionary. By Armin Heymer. Pp. 237. (Paul Parey: Berlin and Hamburg, 1977.) DM28.

A dictionary in three languages (German, English, French) such as this one is useful to both students and research workers if it contains a wide enough selection of terms. I carried out a quick test by opening a recent textbook of animal behaviour at two randomly chosen pages. The Dictionary scored only a 40% success rate on the first ten technical terms encountered. Territoriality, echolocation, circadian rhythm and orientation were included and adequately defined, but habituation, phonoresponse, species recognition, arousal, sexual selection and selective attention were not listed.

Admittedly this is a small sample, but several of the missing terms are very common in ethological literature.

The dictionary does, however, score well in including some obscure terms with which I was not familiar. "Night dancers" are "bees that dance at 3.22 a.m. with only 12.5° error in the waggle dance", and equally intriguing "shag time" is apparently slang for "breeding season in hares and rabbits".

In general, the technical terms included in the dictionary and the way in which they are defined very much reflect the Lorenzian school of ethology, so that the dictionary might prove useful to those wishing to delve into the earlier German literature. Other users may find the range of terms covered too limited for the book to be worth buying as an all round aid to translation.

John Krebs is Lecturer in Zoology at the Edward Grey Institute of Field Ornithology, Oxford, UK.

Ecological stock-taking

A Nature Conservation Review: The Selection of Biological Sites of National Importance to Nature Conservation in Britain. Edited by D. A. Ratcliffe. Vol. 1. Pp. xvi+401. £35. Vol. 2. Pp. viii+320. £25. (Cambridge University: London, Cambridge and New York, 1977.)

THE many demands made on land in Britain are causing a widespread and significant reduction in wildlife. The purpose of *A Nature Conservation Review* has been to take stock of the nation's species and habitats and to identify those sites of national importance, so that new measures to safeguard them shall follow. The work was begun by the Nature Conservancy in 1965 and involved appraisal of several thousand sites. The process and its results are now published in two volumes.

Volume 1, which is complete in itself, explains the *Review's* purpose and methods, lists those sites which qualify as being of national importance and assesses how far their protection would ensure the survival of our total variety

of flora and fauna. It also provides a concise and detailed examination of British habitat types and their wildlife; this makes fascinating reading and will be invaluable for general reference.

Careful consideration is given to possible shortcomings in the *Review's* scope and methodology. This is of more than intrinsic value. There is a tendency not only in industry but amongst a few planning authorities and statutory agencies (who should know better) to doubt the Nature Conservancy Council's objectivity. *A Nature Conservation Review* will reassure them.

Volume 2 comprises descriptions of the 735 key sites, outlining the features which justify their selection from a total of some 3,500 scheduled over the years as Sites of Special Scientific Interest. Although many of the chosen sites contain rare species, good examples of typical habitats or wildlife communities are also included if the continued survival of the type is uncertain.

Obviously, there is room for discussion on whether the right sites were selected in every case but, accepting that new key sites may yet remain to be found and that others will change in merit, there can be little doubt that

the choice is largely correct. A pity then that, having taken ten years to publish the results of the survey, there has been some failure to amend it in the light of the greatly increased amount of information available in the mid-1970s. This is particularly evident where references occur to some rare birds whose recent status has changed notably.

It is particularly important that *A Nature Conservation Review* is read widely outside the nature conservation movement. Criticisms of details apart, it is a remarkable work which can do the NCC's standing nothing but good. It is also a means to an end: protection of the key sites must be achieved somehow and, as the NCC recognises, there is also a need to pursue more general measures for wildlife conservation throughout the countryside. At least volume one should be seen by all concerned with or by the use of land. It therefore passes comprehension that it has been priced so highly that it may fail to reach much of the readership at which it is aimed.

Mammals of Pakistan

The Mammals of Pakistan. By T. J. Roberts. Pp. 361. (Ernest Benn: London and Tonbridge, 1977.) £35.

PAKISTAN lies astride the interface between the Palaearctic and Oriental faunal regions and, in addition, its fauna includes a small element from the Ethiopian region. The country is a mosaic of diverse habitats from the high montane snowlands of the Himalaya to the hot deserts east of the Indus. These factors are reflected in the richness of the mammal fauna, which includes over 150 species of recent mammals. Recent advances in agriculture and the increase in population have led to a rapid decline in numbers of the larger species and to an increased awareness of the role of smaller animals as pests and public health problems. An assessment of the current distribution and status of the mammals of Pakistan is therefore timely.

Tom Roberts has produced a comprehensive account of the mammals of the area which will be the standard work for years to come. The volume begins with two chapters on the zoogeography and habitats, and a chapter

on the adaptation of mammals to desert survival. The remainder of the book is devoted to a systematically arranged account of the species with information on description, distribution, status and biology. Keys are provided for the identification of each taxon. Maps, plates and drawings are used extensively to supplement the text. Useful appendices on field methods, a bibliography and a gazetteer are provided, and the book is fully indexed.

There are some weaknesses in the taxonomy which reflect the current lack of knowledge of Pakistan mammals and which cannot be attributed to any failure on the part of the author. The strength of the book lies in the author's painstaking compilation of data on distribution and status and his first-hand knowledge of the biology of the mammals based on his own field experience. The detailed treatment of each species surpasses the level expected in such a comprehensive volume.

The book should be of great value to the increasing number of mammalogists involved in agricultural, medical and conservation research in the area, as well as to the naturalist interested in the fauna of Pakistan and neighbouring regions.

Acridologists' vademecum

Grasshoppers and Locusts. Vol. 2. By Boris Uvarov. Pp. 613. (Centre for Overseas Pest Research: London, 1977.) £16.

ON retirement, Sir Boris Uvarov undertook the preparation of "a synthesis of present-day knowledge of the theory and practice of acridology", and this publication sees the eventual fulfilment of that task after his death in 1970. The first volume covering anatomy, physiology, development, phase polymorphism and an introduction to taxonomy came out in 1966 (Cambridge University Press). This second, posthumous volume covers behaviour (10 chapters) and ecology and biogeography (3).

The longest single chapter discusses the dynamics of grasshopper and locust outbreaks and plagues. Only in this chapter and an earlier section on swarm migrations is the information arranged by species; otherwise, it is organised by topics and truly comprehensive in scope. The book will thus be useful to many people who do not see themselves as 'acridologists' but wish to draw on the large store of information available from the research on these insects. They will not find all they want on any one topic within these 600 pages, 270 text-figures, 95 tables and 24 double-column pages of index, but they will get the gist of it along with a guide to the rest supported by 1,700 references.

Uvarov's colleagues Z. Waloff, R. F. Chapman and N. D. Jago, who edited the text after his death, have added supplementary material to his drafts but have not attempted to write the planned chapters he had not yet drafted, on economic aspects and the principles of control. Instead, they have rounded the book off with what amounts to a testament, a late review paper of Uvarov's on "Current and future problems of acridology", which sets forth his matured views on population dynamics, control and research.

The book may be fairly described as a monument to the author in more ways than one. The huge edifice of modern acridology was built on his inspiration and drive. The book is also very much the man, in its detailed attention to the facts, and to gaps in them, in its exceptional biological span, its scepticism, criticism and proposals for research, and in its sense of continuity between science and practice that Uvarov always displayed, not least in the unconventional naming of his research organisation, the "Anti-Locust Research Centre". As a more important illustration of that same point, the book incidentally goes some

way toward rehabilitating Uvarov's original discovery of phase transformation in locusts as the basis for a strategy of concentrating control operations on 'outbreak areas' where the swarming phase is produced from non-swarming precursors. Both ideas came under a cloud of criticism in the 1950s and 1960s, not least because it turned out that the most notorious species, the Desert Locust, was highly mobile in both phases and did not have just a few, permanent, outbreak areas like the others. By the time this volume was written, however, enough new information had accumulated to show that even in this species phase change or "gregarisation" is crucial in plague development and occurs in geographically identifiable areas, which are indeed larger and less fixed than the outbreak areas of other species but still far smaller than the

vast region subsequently over-run by the swarms.

Uvarov surely went too far in his reiterated hope that the outbreak areas would one day be deliberately altered ecologically for the sole purpose of preventing locusts from swarming, once and for all. Nevertheless, for the more pressing purposes of human settlement, the necessary ecological changes have already occurred in some regions such as North America, and they will doubtless occur in later-developing countries in due course. If the expected result is an endemic grasshopper problem replacing the locust invasions, we are fore-armed with this book.

J. S. Kennedy is External staff member, Agricultural Research Council, and Professor of Animal Behaviour at the Imperial College of Science and Technology, University of London, UK.

Calculating electronic structure

Semiempirical Methods of Electronic Structure Calculation. Part A (vol. 7) Techniques. Pp. 274. Part B (vol. 8): Applications. Pp. 274. Edited by G. A. Segal. (Plenum: New York and London, 1977.) \$47.40 each part.

WITH so many books available on molecular orbital theory it is hard to imagine many gaps in the literature. Nonetheless, with calculations being run increasingly by non-professional theoreticians there has been a need for a consumer guide to the various alternative semiempirical methods. To some extent the two volumes edited by Segal provide this service.

Most of the variants of molecular orbital techniques are the subjects of monographs but here in the first of the companion volumes several methods are summarised, each in about thirty pages. The individual contributors are distinguished advocates of the methods they describe; in particular the chapters on the PCIO and X α methods will be welcomed as providing more convenient summaries than those formerly available. One would wish, however, that for the price the coverage had been more comprehensive. Although neglect of differential overlap and the methods based on this approximation are the subject of one chapter, it would have been helpful to have a full chapter on the MINDO method even if the editor (as is clear from his preface) does not approve of this variant.

The tone of part A is serious and the theoretical basis for semi-empirical theories is discussed in the longest

chapter by Karl Freed. Many users of semi-empirical methods, on the other hand, only seek justification in the quality of predictions made by their calculations. Some of these applications are the subjects of the chapters in Part B.

Again, some well known names contribute. The topics to which the calculations are applied include thermochemistry; excited states of organic molecules; photochemistry; inorganic complexes; spin resonance parameters; solid-state problems; and electron scattering. Any non-specialist with a problem in one of these areas would be very much helped in choosing the most sensible approximation to select and given an honest indication of the quality of results he might expect.

In one respect the two volumes do not quite provide the complete consumer's guide. Many chemists are not controlled by the technique they use but by the molecules they are studying. They are interested in several properties of the same group of molecules, perhaps the vibration frequencies, the pK_a, the conformation and the nmr chemical shifts. A question one is often posed is, "Which method will answer these questions for me?" and at the same time "Just how much computer time is likely to be required?". A complete guide for the non-specialist would contain a set of 'benchmark' problems on model systems with the results from the various approximations compared and timed. Despite this omission the volumes will not rest unused on library shelves.

Room at the top — for whom?

REPORTS on the state of British industry, its use of qualified scientists and engineers, the attitude of young people towards an industrial career and recipes for supposed improvements are now descending on the office in such profusion that we can no longer guarantee even to collect them from our harassed reception before dispatching them, bundled in their thousands, to a company warehouse somewhere outside Basingstoke, there to be pulped. Two recent arrivals, however, somehow crept under the door and so have at least been afforded a cursory glance by our jaded editorial staff. They are 'Education, engineers and manufacturing industry', a report to the British Association for the Advancement of Science by a small investigating team, and 'University-industry relations', the government's reply to some recommendations made by the Common's Select Committee about a year ago.

At that time, we were critical of several of these recommendations, which seemed rather poorly worked out, at least in the case of the proposed revival of the concept of SISTERS, Special Institutions for Scientific and Technological Education and Research, a step in the wrong direction of isolating science and technology from the broader world. The government's response is equally unenthusiastic, indeed its paper as a whole reads like a long succession of "we don't think this is a good idea", "we think this is a good idea and it is already happening", "we think this is a good idea but someone else should do something about it". The someone else is, of course, industry.

But one recommendation commended to industry is not so easily shrugged off. The Select Committee had said that industry should do something about offering attractive salaries and moving qualified personnel in to senior management with the ease that it is done in Germany, France and the United States or by their British contemporaries who are lawyers or accountants. A good generalised knockabout, but the British Association report puts it in much clearer perspective. It is fairly widely known that on an international comparison, British median salaries are low at the shop floor level and get relatively lower the more responsibility is

assumed. A new survey, released in part to the British Association, looks at the way that even these inferior salaries discriminate against the scientist and engineer in productive industry. Median figures (for October 1975) for about 22,000 professionals show that at all ages accountants and lawyers get paid the most, engineers and scientists the least. Even at 25 the accountants and lawyers are £1,000 ahead; by 40 their median is £9,500, that of arts graduates £8,500, that of scientists £7,500 whilst engineers are commanding a mere £6,600.

Maybe the average non-scientist in industry really is much smarter and earns his or her differential, but no-one yet seems to have said so explicitly. More likely the growing differential reflects the expanding opportunities open to the non-scientists as time goes on. More opportunities mean more rounded employees, soon to be fit for even more opportunities. Less opportunities mean more type-casting as narrow minded characters fit only for the backroom and the sales department.

The matter is not so easily laid only at industry's door, however. The government itself employs tens of thousands of qualified scientists and engineers. Their upward path until the age of 40 is fairly well-defined and somewhat better paid than in industry. But thereafter, stagnation. Ten years ago the Fulton report on the Civil Service, recognising the problem, proposed an 'open' structure at the top of the service to encourage some cross movement among real high fliers. In practice this has meant little. Certainly laboratory directors are at least nominally in the open structure, but when one asks about other scientists and engineers who have made the move into more general high level management, the same name or two keep cropping up. Whether the waste of intelligent human resources would be ameliorated by extending the open structure further down the service or by making it easier for the frustrated to retire earlier, who knows? But at the moment the government is in no strong position to commend industry to take more scientists and engineers into senior management when it shows so little inclination to do so itself. □

Refusnik scientists: keeping science alive

Max Gottesman, from the Laboratory of Molecular Biology at the National Cancer Institute at NIH, was one of ten Western scientists who attended the special four-day Jubilee meeting of the refusnik Sunday Seminar in Moscow earlier this year; the seminar dissolved itself for a 'summer recess' in May following official pressure, and reconvened again last Sunday under Viktor Brailovskii. Below, his views of the refusniks' position

FIVE years ago, the first of the refusnik Sunday Seminars on Collective Phenomena met in a Moscow apartment. Refusniks, unlike dissidents who wish to change Soviet Society, are Jews who wish to leave Russia, usually for Israel. In the case of refusnik scientists, visas to emigrate are often refused on the grounds that the applicant is in possession of "classified information". Not only is their emigration forbidden, but their official scientific life is terminated. They are expelled from their laboratories and denied library privileges; even their telephones are removed. The cut-off is usually very effective: none of Professor Benjamin Levich's colleagues, for example, nor any of the students he had trained over the years, spoke to him after he applied to emigrate.

In an attempt to stay alive scientifically, the refusniks meet together in someone's apartment each Sunday afternoon to discuss science. These meetings have come to attract Western scientists invited to Soviet-sponsored conferences, and they present papers; sometimes establishment Soviet scientists discretely listen to the presentations while remaining in the kitchen. But the special Jubilee meeting held to mark these five years was also accompanied by the constant presence of KGB men stationed outside Dr Mark Azbel's apartment, where the seminar was held.

They followed the Western scientists wherever we went. Usually consisting of four men in a taxi, they made no attempt to disguise the fact that we were being followed; they were there clearly to intimidate us. One afternoon, a truckload of soldiers unloaded below Azbel's window and lounged around several hours before leaving. A parked van, left with the motor running and no driver, contained the monitoring devices used by the KGB to follow the conversations in the apartment. Between the sessions, however, matters of a non-scientific nature were discussed, and from these talks and exchanges of written notes I obtained a picture of the present status of the refusnik scientists.

How the refusniks manage to survive varies from case to case. Some had accumulated savings before applying for an exit visa. Of course a long five- or six-year period of refusal cannot be prepared for in this way. During refusal, they find occasional work, sometimes as manual labourers and sometimes as tutors. Unfortunately tutoring positions tend to be transitory; a discrete call from the KGB to a family employing a refusnik tutor usually has the expected effect.

It is clear that the scientists who have entered into refusal have a common motivation: to escape the severe and worsening anti-semitism in Russia. The Russians wish to exclude Jews from the sciences and other professions. At the present time, it is difficult or impossible for a Jewish student to enter a first-rate university. An example: the medical school in Odessa, a city with a large Jewish population, has not a single Jewish student. Thus many Jews are driven to emigrate to assure their children equal educational and employment opportunities. Current Soviet anti-semitism comes after a long period of relative tolerance. A generation of Jews has been assimilated, and the refusniks find themselves without an inheritance of Jewish culture.

They are anxious to regain their heritage—and to learn Hebrew—in the face of severe pressure from the authorities. It is no accident that the two refusniks currently in prison, Joseph Begu and Anatolii Shcharanskii, were the most active in disseminating Jewish culture. And yet, in spite of the threats, there were several refusniks at the seminar I attended wearing Israeli pins in their lapels.

Why don't the Soviets just let the refusniks emigrate? In fact, some are permitted to go; but the rate is slow, and getting slower. The Soviets fear that an easy emigration policy will result in Jews as well as other national groups demanding, *en masse*, to emigrate, thus threatening the stability of the State. Also, the Jewish scientists have a special problem. The justification of the Soviet system is 'scientific'; Marxist-Leninist analysis of history and economics has proved, in a manner as certain as $E = mc^2$, that Soviet society is structured correctly. For a scientist to desire to emigrate is unthinkable. It should be mentioned that the only valid reason for leaving Russia is to rejoin one's family abroad.

What can be done? In view of the fact that the Soviets greatly value scientific contacts with the West, certain courses of action are feasible. In particular, international meetings and exchanges can be used to help the refusniks. Refusnik scientists wish to participate in these open meetings and could be invited. If such participation is denied by the authorities, Western organisers should consider either the possibility of moving the meeting from Soviet territory, or of limiting Soviet participation in meetings held in the West. In the case of the International Genetics Conference, to be held in Moscow in the summer of 1978, a precedent has been set. A prior conference was moved from the United States to Canada in the 1950s when the US State Department refused to issue visas to certain foreign scientists.

Publicity is essential to keep the refusniks from simply disappearing. Official Soviet visitors should be reminded that the treatment of refusnik scientists threatens Soviet-Western exchange programmes. Since visitors are invariably debriefed by the KGB on their return, this is an effective means of reaching the Soviet authorities. It should also be remembered that the critical decision as to whether a refusnik's work is 'classified' is made by his departmental superiors, or the chairman of his department. These are often the very scientists who are sent to Western conferences and exchange programmes.

Finally, it should be stressed that scientists visiting Russia are warmly welcomed at the Sunday Seminar, and are doing a great service to the refusniks by attending. For addresses and other information contact the Committee for Concerned Scientists, 9 East 40 Street, New York, New York, 10016. □

Sunday Seminar scientists in November 1976

Tethering the tide

T. L. Shaw examines the prospects for harnessing tidal energy in the Severn Estuary

FACED with a possible world fuel shortage, the UK Department of Energy (DEN) is taking stock of domestic energy sources. Together with industry, it has already provided money for scientific and technical studies on the contribution four 'renewable' sources—wave, solar, geothermal and wind—could make to meeting future demands. It is now looking at the part tidal power could play.

The DEN's recently-released Energy Paper number 23, which discusses three commissioned reports on harnessing tidal power in the Severn Estuary, concludes that although tidal schemes are technically feasible, cost and the long time estimated for construction may rule them out. Nevertheless, studies to identify one or more schemes for wider appraisal are now being seriously considered.

The tides have the particular advantage of far greater energy density than the other renewable energy sources. In the Severn Estuary, for example, tidal energy is thirty times denser than power derived from average waves on the UK's Atlantic seaboard. Individual tidal schemes could produce many thousands of megawatts of electricity but, for maximum benefit, they would have to be integrated efficiently with other (essentially thermal) generating plant.

This enormous potential could be harnessed by building a dam to separate part of the coastal inlet from the sea. Turbines that might resemble conventional hydro-electric propeller machines would be set in fully sub-

merged tubes passing through the barrage. A difference in water level either way across the barrage (during flood and ebb tide) would create flow through these tubes and so an electrical output from the slowly rotating turbines.

In the Severn Estuary, the UK has perhaps the best site in the world for producing electricity from tidal power. At least 10% and as much as 20% of the UK's present electrical needs could be met from a barrage either within the estuary (10%) or seaward in the Bristol Channel (20%). These percentages are comparable with those currently supplied by nuclear installations and oil and gas-fired stations respectively.

But this is not simply a case of one electrical source competing against another. Each has characteristics which influence its most efficient hence preferred use: nuclear stations, for example, should run continuously, whereas gas turbines are best run in short bursts at times of high demand. The output of aerogenerators is fairly regular over a period of hours and maybe days while that of wave generators may be consistent on an even longer scale. Tidal output suffers from being intermittent but it is accurately predictable. There is no reason, however, why each source, provided that it can be commercially developed with respect to its operating value, should not contribute to the total generating network.

Recent studies

Last year the DEN commissioned two investigations into aspects of the Severn barrage. The questions the investigations set out to answer were: is construction and closure of a barrage

technically feasible? how long would it take to build? what would be the likely cost? and what would be the effect of the barrage and its operation on tidal range? They were issued respectively to the Netherlands Engineering Consultants Foundation (NEDECO), which has great knowledge in maritime affairs especially coastal protection, and to the UK Department of the Environment's Hydraulics Research Station (HRS), which, since it was established some 30 years ago, has worked extensively on coastal hydraulics.

For their studies both NEDECO and HRS chose to consider barrages in positions between Cardiff and Weston-super-Mare, where 10% of the UK's present electrical demand could be produced. Most attention was paid to proposals by Professor Eric Wilson of Salford University (the simple single-basin, tide-related scheme) and myself (the more complex two-basin arrangement providing storage and giving power by day as required. Summaries of each study are as follows.

NEDECO

In the absence of adequate field data, NEDECO was obliged to make a number of assumptions about hydrodynamic conditions at the chosen barrage site, in particular data describing wave climate. The serious lack of adequate geological and sedimentological information was met by surveys carried out by the UK Institute of Geological Sciences. It identified exposed limestones and marls over a much greater proportion of this part of the estuary than the previous scant scientific data had suggested. Localised fine deposits, mainly sand and shingle are thought to be shallow, implying a firm foundation throughout for a barrage.

Based on "the impressive experience obtained in the planning and execution of the Delta Works (in Holland) together with the immense increase in know-how and expertise of recent years in the offshore industry," NEDECO is optimistic that civil engineering aspects of the barrage could be carried out satisfactorily, though it appears to have underestimated the magnitude of the challenge successfully met by British industry of placing concrete caissons in 150 m of water in the remote and exposed North Sea, compared with the task of siting correspondingly much smaller units in no more than 30 m of sheltered water in the Severn Estuary.

But the siting of caissons for the barrage raises some problems not met in the North Sea, in particular the strong currents that accompany the

T. L. Shaw is in the Department of Civil Engineering, University of Bristol.

high tides. The positioning and sinking of caissons in currents exceeding 3 metres per second could prove hazardous, but given proper planning they could be placed during slack water 'windows' which occur frequently and predictably.

Doubts also exist on the accuracy of NEDECO's estimates of extreme wave heights at the chosen barrage site. Unfortunately those local measurements that have been made are for such short periods that the validity of statistical extrapolation is questionable. Another factor is the apparently sheltered position of the barrage compared with that of the one long-established wave recorder 100 km seawards. In the absence of other evidence, however, NEDECO's estimates cannot yet be dismissed.

Extra cost, NEDECO claims, will have to be incurred in building offshore-dykes to protect the turbines in the single-basin barrage from direct wave attack. If a two-basin scheme is adopted, however, the problem need not arise: the second basin would essentially serve the purpose of offshore dykes.

NEDECO estimates that the civil engineering task alone for the two-basin scheme will require four years of preliminary study and 16 years to build. This could be taken as sufficient to rule out the scheme on economic grounds. But it does agree that the timescale could be shortened, though with an increase in capital cost. By contrast, the UK construction industry feels that a timescale of about eight years, similar to that of most thermal plant, is realistic.

An alternative to help save on interest charges, would be to secure some energy from the scheme long before completion, increasing it as the scheme advances. The full output capacity of the scheme then would not be suddenly available to the network, and would permit efficient integration. Hence 16 years may not be unreasonable, though the various electrical merits of phased construction of a barrage are not yet clear; studies well advanced at the University of Bristol, funded by the Science Research Council, are exploring the possibilities. The concept of a two-basin barrage scheme developed first to operate in the 'single-basin' mode, as discussed earlier, may make good sense. NEDECO's study did not consider phased integration.

Hydraulics research station

The general lack of field data also made it difficult for HRS to define its problems, especially the seaward boundary conditions for its study's two-dimensional mathematical model.

Coastal and offshore tide modelling has moved a long way forward in the past five years, since it was recognised that local boundary changes can have effects at a considerable distance depending on their extent and the local tidal behaviour. Although earlier models, including that used by NEDECO, assumed that conditions at the seaward end of the Bristol Channel would not be unchanged by a barrage, HRS included the Celtic and Irish Seas in its model.

It is perhaps unfortunate that the 'large area' model of HRS predicts that the barrage will marginally amplify the tides whereas 'small area' models suggest the opposite. The right answer must be found, not least because, as matters now stand, the accuracy of both is under question.

But these doubts hide two aspects of the work of HRS. First, that it is something of a pioneering exercise in its own right and deserves recognition as such even if deficiencies later emerge. Secondly, an increase or decrease of tidal amplitude by up to 1 metre or so is sufficiently small in real terms to conclude at this stage that a barrage operating in the region Cardiff-Weston will not destroy the natural energy it is designed to harness. Although it must be a matter of some urgency to resolve why different mathematical models give different answers, and in particular to produce a model giving the right answers, it would only be wasteful to repeat these studies without knowing where the barrage might be sited, and understanding pump and turbine operation and induced oscillations (seiches) in the enclosed basin(s).

When reporting 'The situation in 1975', Energy Paper number 23 quotes that the Secretary of State's Advisory Council on Research and Development for Fuel and Power (ACORD) and the DEN came to the opinion that "in view of the uncertainties surrounding some of the aspects of the studies (of the barrage, as previously carried out by others), a more vigorous examination should be undertaken of certain key technical questions in order to clarify the situation further".

Of the three questions posed, the work of NEDECO and HRS should have answered two to the satisfaction of ACORD and the DEN. I hope that the third, namely "what would be the environmental consequences, and could they be quantified in cost terms?", will also be answered in similarly sufficient detail by the book *An Environmental Appraisal of the Severn Barrage* (second edition).

The next step is aptly stated by NEDECO: "The chance exists that we could contribute towards the

● The future for tidal energy in Britain has at last been clarified. There have been strong calls for further studies by the House of Commons Select Committee on Science and Technology in its fourth report published last week and at the Secretary of State for Energy's 'Forum on the Severn Barrage', held in Bristol the week before.

Although the potential of the tides and the consequences of a barrage are fairly well understood, gaps in knowledge remain. The Select Committee, which has come out in support of tidal energy ahead of the other renewable sources, proposes that an independent Severn Barrage Committee, composed of technical, financial and administrative experts, be set up to assess Severn Barrage schemes and deliver a studied opinion to the Secretary of State. It highlights the unresolved problems of choosing a barrage location and method of operation and suggests that other studies should also be done. Outline costings, provisional construction methods and timescales should be sought by a "fairly early date . . . to command general agreement".

The Secretary of State's 'Forum' provided the DEN with first-hand evidence on most of the many relevant topics, for example energy cost/benefit estimates, environmental consequences and the widespread employment, industrial, commercial and recreational merits of the project. Though opposition was scarcely evident, many speakers were cautious because so much remains unclear. Summing up Mr Benn, the Secretary of State, said that all relevant interests must be represented in the next important phase of project definition and that a staged approach allowing for reappraisal of points was essential. (The case for a pilot installation has wide support.)

While the DEN may not altogether deserve the Select Committee's criticism of being "excessively timid" about tidal energy, its scale of research funding must increase 100-fold if these unified calls for action are to be answered. The national benefits at stake ought to make it easy for a cabinet to persuade the government to provide the still-modest sum now needed.

creation of a very clean type of energy production, the value of which can only increase because of its increasing scarcity on a worldwide scale". British industry is ready to contribute towards these investigations.

The capital cost estimate of up to £4,000 million quoted in Energy Paper number 23 might imply an expensive power station, but current unit costs for other plant tend to refute this. However, simple comparisons are dangerous when like objects are not being equated. It is much better that the next phase of study of the barrage should be carried out to identify its real electrical (and other) benefits before economic judgments are reached. A comprehensive but objective programme for the next 18 months is needed. □

OTS

Second chance

Last week, Europe's Orbital Test Satellite was destroyed shortly after launch. Judy Redfearn reports

EUROPE'S hope for a sophisticated system of communications satellites by the early 1980s might well have gone up in a cloud of smoke with the European Space Agency's (ESA) Orbital Test Satellite (OTS) last week, had it not been for ESA's foresight. In the wake of two mishaps by NASA earlier this year—its failure to launch Geos into the correct geostationary orbit and an accident with a Delta launcher which meant that OTS could not be launched in June as planned—ESA made sure that it went ahead with a plan to take out insurance cover for the launch of OTS and the integration of a second flight model. The insurance, to the tune of \$29 million at a premium of about \$2 million, was placed by Bowring of London throughout all the countries taking part in the project in proportion to their financial commitment to it.

As fate would have it, ESA's precaution was extremely wise. Seven miles above Cape Canaveral's main launch pad and only 54 s after a seemingly perfect launch, the Delta 3914 carrying OTS began to disintegrate and exploded just prior to a signal of destruction. The insurance cover, however, gives Europe

another chance. As with all satellite missions, ESA built a second OTS identical to the first which could be ready for launch by next March. This means that the OTS test and experimental programme could still be compressed to be completed within the original time.

A second chance is particularly important for the OTS because, unlike Geos, it has considerable commercial potential. It is Europe's first communications satellite and is the forerunner of four similar satellites which are planned for launch by Ariane, Europe's own launcher which is still being developed, between 1981 and 1990. They will carry a large part of intra-European telephone, telegraph and telex traffic and will relay European television programmes. The OTS's task is to test much of the equipment which will be used on the operational satellites and to provide a pre-operational European traffic capacity.

The decision on whether or not to go ahead with the second OTS launch early next year will probably be taken by ESA officials this week. As the only launcher available to do the job is the American Delta 3914, they are probably hoping for some assurance from the Americans that a similar accident is extremely unlikely to happen again. Although the success rate of Delta launchers is very good—134 have been launched since 1966, 122 of them

successfully—the history of the Delta 3914 is not so happy. Three of them have been launched and the OTS marks the first failure: but the launcher which was damaged in May this year and caused a three-month delay to the OTS programme was also a 3914. In that case, one of the booster rockets fell off the main Delta vehicle because of a defective bolt.

Late last week, NASA set up a seven member team of inquiry to look into the incident. It hopes to find out whether or not the fault lay in the basic Delta vehicle or the attached rockets before 13 October, the planned launch date of the International Sun-Earth Explorer (ISEE) in which ESA has a large interest. If the fault is found in the Delta 3914's strap-on rockets then it should be safe for the ISEE to go ahead as planned as the Delta 2914, on which it will be launched, uses a different rocket configuration.

Until late 1980 when the Ariane launcher is ready for use, ESA will have to launch its satellites on US vehicles. By the early 1980s, however, there may be another option if a West German company, Orbital Transport- und Raketen-Aktiengesellschaft (OTRAG), is successful in developing its own heavy launch vehicle. So far, it has spent \$30 million on the project and hopes by 1981 to be launching satellites from Zaire. ESA will not discuss the possibility of using OTRAG launchers until it knows whether they, and Ariane, will work. □

BRITAIN

Timely delay

The Council for Science and Society has recently published a report called The Acceptability of Risks. Alastair Hay reports

IN spite of a 12-month delay, the Council for Science and Society's report, *The Acceptability of Risks** published last week has arrived at an opportune moment: the explosion at Flixborough, and the release of tetrachlorodibenzo-p-dioxin at Séveso are recent memories, and the public enquiry at Windscale is still in progress. Its findings and recommendations will certainly provoke heated debate.

Risks, it claims, are very unevenly distributed; those in the UK at greatest risk are "concentrated in the homes,

communities and workplaces of manual workers and their families". In a harsh message, the report states that positive action to remove this inequality is urgently needed, and that it regrets that "hazards of all sorts have been shamefully neglected in scientific and technological research".

The report also points out the potential danger of regulatory agencies being weakened and rendered ineffective by financial constraints and inappropriate standards. Indiscriminate use of the terms 'safe' and 'acceptable' are to be avoided, it says, as both are ambiguous and subject to a wide range of individual interpretation.

Appendices deal with specific issues such as nuclear radiation, ammunition and explosives, the hazards of asbestos, and the Flixborough Court of Enquiry. In a disturbing commentary on the conduct of the Flixborough court investigation, one of the authors of the

report, Brigadier R. L. Allen, claims that the enquiry was too narrow; that some relevant evidence was not considered; and that statements by the court to the effect that "Nypro [owners of the Flixborough plant] were safety conscious" were inappropriate in the light of the evidence presented. He says that this is illustrated by Nypro's breach of licensing arrangements when it stored 43 times more inflammable fluid on site than it was entitled to do: a fact which severely hindered rescue operations after the initial explosion.

In conclusion, the report recommends areas of investigation to be considered by working groups and which could provide useful information for 'risk management' in the future. Also suggested is the possibility of the appointment of 'risk advisers' in particular occupations and localities.

A few of the abuses the report refers to have been dealt with during its delay at the printers. Few will consider this more than a minor fault. □

**The Acceptability of Risk* is available from Barry Rose (Publishers) Limited, Little London, Chichester, Sussex, £5.00.

USA

Battling against the inevitable

Years of hitherto unsuccessful effort in the US Congress have culminated in a bill providing for an increase in research on earthquakes. Chris Sherwell reports from Washington

DEVELOPMENTS now reaching a climax in Washington may not do for earthquake research what previous much-publicised efforts did for space and cancer research, but the comparison may not be entirely inappropriate. The fanfares may be absent and the vistas uncertain, but an agreed commitment in principle which also has legislative form now promises a long-awaited boost for work in an exciting area and marks an important move from disaster relief to disaster prevention.

The latest step along the tortuous path to a comprehensive coordinated programme to reduce the hazards posed by earthquakes came last week when the House of Representatives approved by a margin of 229 votes to 125 an authorisation bill on which two House committees had reported. The bill was due to go back to the Senate late last week for consideration of the minor differences from the Senate version

passed earlier this year, and was expected to find its way to President Carter's desk for signature shortly thereafter.

The bill, which when enacted will be known as the Earthquake Hazards Reduction Act of 1977, is designed to reduce the risks to life and property of future earthquakes in the United States. The logic underlying it is simple: earthquakes are inevitable, and population increases and urbanisation enhance the dangers they pose. To minimise both the risks and potential losses, a coordinated programme to increase research and to help apply its findings and generally improve the readiness of vulnerable areas for emergencies is necessary. The bill creates a \$215-million three-year federal programme to do just that.

Though expenditure is scheduled to begin at the start of the coming financial year (fiscal year 1978) beginning on 1 October, the money must still be appropriated in a separate process. In the meantime the agencies slated to use it must rely on appropriations already granted them for that period. The two major agencies involved—the National Science Foundation (NSF) and the US Geological

Survey (USGS)—expect to feel the improvement over recent years quite soon, however, because the appropriations already granted are based largely on the same formulation used in drawing up the bill.

That formulation was contained in a report of a joint advisory committee chaired by Dr Nathan Newmark and published a year ago. Entitled *Earthquake Prediction and Hazard Mitigation: Options for USGS and NSF programs*, the report outlined low, intermediate and high levels of support for earthquake research, all of which were higher than funding levels in past years. The intermediate level, which President Ford used in his proposed budget for fiscal year 1978 and which President Carter retained in his revisions, provided for expenditure of nearly \$54 million, an increase from \$22½ million the previous year. This was split approximately 52 : 48 between NSF and USGS (in favour of NSF). Under the bill passed by the House, some \$55 million would be split 50 : 50.

Going by the breakdowns given in the Newmark Report, the two agencies would each spend about 10% of their 1978 allocations on fundamental studies of the causes and mechanisms of earthquakes. NSF does not expect to see any great difference in this area, but on the engineering front, which

No long encounter with Halley's Comet

THE National Aeronautics and Space Administration (NASA) has reluctantly abandoned an ambitious and expensive plan to conduct a close-range study of Halley's Comet as it swings around the Sun in 1986. The plan would have entailed launching a spacecraft in 1982 on a complicated journey, culminating in an extended rendezvous with the comet three and a half years later.

According to NASA officials, development of the spacecraft together with a new propulsion system to manoeuvre it into Halley's orbit would have cost \$500–600 million. In particular, considerable outlays would have been needed in the next two years to make the 1982 launch date, and NASA simply doesn't have enough money in its budget.

Consequently, the agency has been forced to drop the idea of paying an extensive visit to Halley's Comet, and it is now looking into less expensive plans to launch a spacecraft to make a brief encounter with the comet soon after it emerges from behind the Sun. In addition, NASA is con-

sidering the possibility of developing a spacecraft to make a lengthy visit to the comet Encke in 1987.

The decision to forego the chance of a long encounter with Halley's Comet will be a major disappointment to many space scientists. Comets have recently come under serious study because they may provide some clues to the origins of the universe. According to one widely-held theory, they are like giant dusty snowballs, made of condensed matter from outside the solar system. As they swing past the sun, heat vaporises material from the comet's nucleus, which then forms the so-called tail.

A trip to Halley's Comet, culminating in an extensive visit, would have been a difficult proposition, however. The chief problem is that the comet orbits the Sun every 76 years in the opposite direction from the Earth, and a complicated series of manoeuvres would be required to bring a spacecraft to the same path and speed as the comet.

For the past year, NASA has been looking into two propulsion systems

which could provide the required manoeuvres. The first, a so-called solar sail, would have consisted of an immense plastic sheet, deployed from the spacecraft on booms, which would act like a sail in the solar photon stream. The second idea, an ion drive system, would involve the ionisation of mercury vapour, which would then stream out of the back of the spacecraft to provide thrust. Last week, NASA announced that it has chosen the ion drive system which will be developed for a possible mission to visit Encke in 1987 and which will also be used to power future interplanetary probes.

Though the plan to rendezvous with Halley's comet has been abandoned, NASA may still launch a spacecraft in 1985 to fly close to the comet and pass through its tail. Such a mission would not require a special propulsion system because complicated manoeuvres will not be required to match orbits. It would consequently be much cheaper, but the scientific benefits would also be much less.

Colin Norman

would take some 60% of the NSF allocation, research funding will almost double in the coming year. This effort will focus on the design, planning, construction and use of various man-made works to resist earthquakes. Another 20% of NSF funds would probably go to related socio-economic and policy areas.

On the same basis, USGS is likely to devote about half its allocation to the development of methods to predict the time, place and magnitude of future earthquakes. Another 35% or so would go on assessing earthquake hazards, while a small amount would be spent on studies of artificial earthquake inducement.

As for fiscal years 1979 and 1980, the 50:50 split between the two agencies would continue for budgets totalling \$70 million and \$80 million; the breakdown could be expected to follow broadly the same pattern. If the patterns of spending are predictable, however, the scientific results are not. Recent scientific progress in the field has probably assisted the bill's passage; reliable earthquake prediction seems more likely than ever before.

Of equal importance for the bill, however—apart from an unsubstantiated sense that more earthquakes than usual have struck in recent years—was the support given by the Carter Administration, notably by the Office of Science and Technology Policy in the White House, which is headed by the President's science adviser, Frank Press, himself a geophysicist. Indeed, the bill reflects many of the Administration's preferences. When it came out of the House Interior and Insular Affairs Committee, under which USGS falls, the important difference from the bill it received from the House Science and Technology Committee, and which put it in line with the Senate version, was that it contained no specific institutional proposals. The bill it received had suggested an Office of Earthquakes Hazards Reduction, a National Advisory Committee, and an Earthquake Prediction Evaluation Board.

Given the President's desire for flexibility while pursuing plans for government re-organisation, these suggestions were premature. Accommodatingly, the bill thus provides simply for designation of a "lead agency", and the usual establishment by the President of roles and goals.

On Capitol Hill not all reactions

Controlling technology flow

QUESTION: how does a technologically and militarily sophisticated superpower, which is committed to free trade principles, contain the contribution that its much sought-after exports might make to the military capability of potential adversaries?

Answer: it's a problem. The latest round in a recurring debate in the United States on the matter came immediately before the Labor Day weekend at the end of August, when the Secretary for Defense, Harold Brown suddenly released a five-page memorandum sent to various officials in defence-related agencies.

Cast as an interim policy statement on controls over the export of US technology, the memorandum draws on the recommendations from the Defense Science Board Task Force, published last year as the so-called Bucy Report (see *Nature*, 15 April 1976). This indicated that controls over the flow of strategic or "critical" technology to Communist countries had broken down in recent years, and suggested that the United States should refine the list of relevant technologies and apply sanctions where they were unwarrantedly passed on, directly or otherwise.

The "interim internal guidance" which the Brown memorandum provides for the Department of Defense (DOD) covers exports both to allies and to potential adversaries. It says DOD will support the transfer of critical technology to countries with which the US has a major security interest where this can strengthen collective security, contribute to NATO standardisation and enhance the return on R&D. But with both allies and other non-Communist countries, DOD will also assess the recipient's "intent and ability to prevent either the compromise or the unauthorised re-export of that technology", relying on the intelligence and security communities to help discover any breaches. Violations would result in sanctions.

Regarding exports to potential adversaries, a "presumption for recommending disapproval" will operate where these involve a revolutionary advance in defence-related technology. But where they involve end

products not of strategic importance or with virtually unextractable valuable technology, DOD will normally recommend approval. Either way, the key consideration would be the recipient's military capability.

According to the memorandum, the Department of Defense will be asking the Commerce Department to change present regulations so that exports of critical technology to all countries would require a valid licence; DOD will also recommend a streamlining of application procedures to minimise delays. In addition, DOD will suggest that the State Department negotiate new measures to control the flow of technology to Communist countries with the Consultative Group Coordinating Committee (COCOM), which is a group of NATO countries and Japan.

The primary objective in all this, of course, is to protect US lead times in the application of technology to military capabilities. The hope is that this will be more readily achieved through an emphasis on technology rather than end products, and by having the policy cover all countries using faster procedures. The provision allowing for DOD "recommendation" will help here; so too will the plan to maintain a continuously updated list of critical technologies. No indication was available, however, regarding the timetable for a fully national policy; that will bring in other government departments.

In the meantime, one minor worry remains. A covering letter to the Bucy Report described, as potentially an "area of concern", the scientific exchange agreements under which scientists move between the USA and the Soviet Union. The Brown memorandum does not take this matter up in any real detail, but says that when the potential for "inadvertent transfer" is high, DOD will recommend restrictions "on the amount, extent or kind of interpersonal exchange". Such exchanges are already subject to certain procedures and regulations, however, and the Head of the Exchanges Office at the State Department says the memorandum implies no changes.

Chris Sherwell

Colin Norman leaves Nature this week to go to the Worldwatch Institute in Washington. He has been our Washington correspondent for about six years, having previously worked in the London office. With his departure the journal loses a distinguished observer of the scientific scene.

were positive. Senator Alan Cranston of California, who has sought earthquake legislation for five years, naturally welcomed passage of the bill as a "historic step"; last year he saw his own bill, already passed by the Senate, die in the House at the end of

the session. But in the House a Maryland Republican was more caustic: a Congress which could not detect an inflationary impact in spending a quarter of a billion dollars, he suggested, "could not possibly detect an earthquake". □

PAKISTAN

Voice for science

Academics and industrialists have been discussing the role of R&D in Pakistan. Azim Kidwai reports

PAKISTAN has remained in a state of political flux since the general election last March when Mr Zulfikar Ali Bhutto's Peoples' Party won a doubtful victory. The army takeover and the introduction of martial law in early July has also had its sobering effects; but in the face of this and the prospect of another, perhaps emotional, election next October, Pakistan's R&D effort seems unusually resilient.

This is reflected in the fact that the consensus reached by important representatives from education, science, technology and industry at the National Seminar on Cooperation between Universities, Research Institutes and Industry, recently held in Karachi, may have significant effects on the promotion of R&D in Pakistan. The seminar was unique in that it was organised by the Federation of Pakistan Chambers of Commerce and Industry and was attended, among others, by three vice-chancellors, the Chairman of the Pakistan Council of Scientific and Industrial Research, the Secretary of the Ministry of Science, several heads of research institutes and many leading industrialists. It was, in fact, a sequel to a UNIDO Adhoc Expert Group meeting on the same subject, which was held in Vienna last December and in which Pakistan participated.

The Karachi moot, however, reflected new trends in Pakistan one of which was that the private sector of industry, which had hitherto been largely apathetic towards scientific and industrial research, had started showing awareness of its importance. A fruitful outcome of the three-day deliberations was the formation of a National Research Utilisation Board by the Chambers of Commerce and Industry, consisting of representatives from universities, research institutes and industry itself. It is to promote industries based on indigenous research.

The main bottleneck so far in making use of research has been the absence of any proper mechanism to rope industry into the R&D effort. The entrepreneurs in industry have largely settled for 'turn-key' jobs on proven products and for technology developed by foreign firms. The element of challenge and the calculated gamble in using products and processes developed locally has rarely been acceptable to

the industrialist.

The position now appears to have changed considerably with the tight balance of payments making it imperative to exploit indigenous raw materials and local technological talent. The dearth of foreign exchange has had its repercussions on the industrial sector. For the first time, industrialists are coming round to the view that the limited resources of the country call for an organised approach based on self-reliance and for the mobilisation of the meagre R&D resources. The technology which will be applied, however, will need to be appropriate to the physical, human and capital resources available.

Until now, there have been two weak points in the structure. The universities have been dominated by academics and have contributed almost nothing to applied research and the development of industry; and there has been a lack of interest on the part of industry in the government's R&D effort. The recommendations which came out of the seminar are for more collaboration between industry and research institutions and industry and the universities.

Another suggestion to be accepted at the seminar was that research and development centres should be gradually created within industrial enterprises and that the R&D function should be part of feasibility studies and the design of new large plants. To promote applied research in the universities, the Universities Grants Commission and the Pakistan Science Foundation are likely to give liberal financial support for collaborative research, while the Government may help by providing industry with incentives, such as tax exemption, for sponsoring research projects. Research in the universities suffers from inadequate funds; if more money were available, they could work for technological progress as well as pure knowledge.

Dr Salimuzzaman Siddiqui, a chemist, stressed the point that pure and applied research cannot easily be demarcated. So far as problem solving is concerned, priorities cannot be allocated under rigidly defined categories and there should be a massive but carefully phased multidisciplinary programme. Most of the participants felt strongly about another point raised by Dr Siddiqui, namely that Pakistan was spending barely 0.2% of its gross national product on R&D compared to 2-4% in many advanced countries: there was need for a major change. □

CHINA

Desert song

LIKE the United Nations, which organised an intergovernmental conference on desertification in Nairobi earlier this month, China has been taking an interest in the problems of desert control. Over recent years two national conferences on desert control have been held and several major works on aspects of desertification have been published, including 'An outline of Chinese deserts' and 'Summary of mass experience in China's desert control'. Two further works, 'Control of sand destructive to farmland' and 'Protecting railways against sand' are to be published soon.

Using the findings reported in these publications as guidelines, prefectures, counties and communes in six provinces and autonomous regions have drawn up their own plans to combat or even reverse desertification taking into account local conditions. The now established causes of desertification—unplanned irrigation, excessive tree felling, overcultivation, overgrazing, with drought being a condition but not a fundamental cause—are supported in ancient Chinese records. Measures taken to tame deserts include:

- planting wind resistant shrubs on the windward side of land threatened by encroaching deserts and tall trees near farmland. When the wind blows at average speeds, the length of the protected area is some twenty times the depth of the forest shelter belts. Criss-crossing tree belts in oases provides further protection against the wind.

- creating new oases by building reservoirs to store seasonal flood water from streams and lakes and using melted snow from the mountains or underground water to irrigate the reclaimed land before planting trees to protect it.

- developing pasture land for animal husbandry in deserts with fixed sand dunes or only interspersed shifting sand. Forage bases can be established on flat land in between sand dunes where water resources are relatively abundant.

Such measures are important especially as 11% of China's total land area, about one million square kilometres, is desert. Just over half of this is dune desert, the rest being gravel and other types. The Academia Sinica runs a desert research institute which studies desert distribution and type, the processes which form them, their natural conditions and ways of combating destructive sandstorms and using water and soil resources in sandy areas and in reclaimed land. It also publishes a quarterly journal *Desert Research*. In addition, the state has set up experimental forest farms and twenty demonstration stations for desert control. Many species of plants, which will survive in the desert, have been grown at the stations.

T. B. Tang

IN BRIEF

EEC report

ENERGY, uranium prospecting and the use of weedkillers containing dioxin were topics for questions last week at the European Parliament in Luxembourg. EEC Commissioner, Richard Burke, told the Parliament that the Commission is considering the possibility of including wind energy in the next research programme. The EEC already has plans for building a prototype plant to generate electricity from solar energy and there were suggestions for a comparable unit based on wind energy. However, it was unlikely, according to Burke, that wind energy could be more than peripheral because of the few areas within the EEC where

it would be suitable. Initial results for uranium prospecting in the EEC were reported as encouraging and those for Greenland as good.

There was concern over the use of weedkiller 2,4,5-T, which may contain traces of dioxin, the chemical released around the North Italian town of Seveso following an explosion at a chemical factory. The weedkiller is presently allowed in all EEC countries except Italy, Antonio Giolitti told the Parliament. Limiting its use should be considered following each item of information, he said. The Commission's proposed directive on harmonising safety regulations on dangerous manufacturing industry is to be discussed—

for the third time—by EEC government experts on 13 and 14 October.

Leakey in Europe

To mark the inauguration of its European chapter, the L. S. B. Leakey Foundation has endowed two post-graduate students at St John's College, Cambridge. Named after Dr Louis S. B. Leakey and based in the United States since 1968, the foundation has given more than \$1,000,000 to support the study of man's origins, behaviour and survival. The first task of the new chapter, Dr Bernard Campbell its vice-chairman said last week, will be to raise its own funds mainly to support anthropological research.

A FEW months ago (19 May, page 201) I voiced pessimism about the laetrile movement, but now I am in a more contemplative mood. Eleven State Legislatures have passed measures authorising the sale of laetrile. A most interesting day of reckoning is ahead, because no one, least of all the lawmakers, seems to know what laetrile is. Vials containing the solution are sometimes microbially contaminated. The 'potency' of various samples ranges from 14–87% of claims, and one batch of 'laetrile' capsules was found to consist of dehydrated iced tea, which was probably an improvement, because iced tea, unlike amygdalin ('street laetrile'), does not liberate cyanide in the digestive tract. Dr Gerald Lewis fed experimental animals with laetrile and sweet almonds; the almonds contain beta-glucosidase, which hydrolyzes amygdalin, and the animals died of cyanide poisoning. A child died similarly when she ate her father's laetrile tablets. I pointed this out to a pro-laetrile California state senator, and he told me that aspirin kills, too.

I am somewhat encouraged by the fact that the 'establishment' is finally bestirring itself. The Director of the National Cancer Institute, who opined that Ernst Krebs' theory of laetrile action was a great idea, and he wished it would work, has now departed; the US Surgeon General, Julius Richmond, now says that laetrile is useless and may be dangerous.

The best recent news stories were those concocted by the laetrile proponents at hearings before Senator Edward Kennedy on 12 July. Dr John Richardson, whose licence to practise medicine has been revoked, said that he, Ernst Krebs Jr and Robert Bradford were the victims of a conspiracy

by "the major oil and drug companies, the Food and Drug Administration (FDA), the American Medical Association, the National Cancer Institute, the American Cancer Institute"; he also suggested that the Rockefeller family was involved. The witnesses, including Bradford, were

Iced tea or laetrile?

THOMAS H. JUKES

unable to write the formula for laetrile "on a piece of paper", but Bradford, an engineering technician, said that "orthodox medicine was not qualified" to evaluate clinical tests of laetrile. Krebs, who is appealing a six-month jail sentence for violating his probation by selling laetrile, was reported as seeking to leave the impression that he was promoting laetrile for "purely humanitarian reasons". Carol Hehmyer, who prosecuted him, testified that he and his associates in San Francisco took in more than \$500,000 in two years by "selling laetrile and other outlawed medicines".

The 'victimisation' of Richardson, according to newspaper articles, seems to be rendered tolerable by his income (he grossed \$783,000 in 1974) and his opulent lifestyle. Bantam Books have printed 200,000 copies of his new book, *Laetrile Case Histories*. The FDA caustically pointed out in 'The Federal Register', 5 August, that Richardson's book states that he threw out the cases with "the weakest medical histories" and described only 62 out of 4,000 patients! In his book he also tells how he got the idea of laetrile promotion from Ernst Krebs Jr, whose biochemical theories, exposed as fantasies by Professor David Greenberg in 1974, served to convince Andrew McNaughton Jr, a former Canadian test pilot who is the leading entrepreneur of laetrile in Tijuana.

The scientific exposition by Krebs took place, according to McNaughton, in conversation at a chance meeting in a drugstore in Miami some years ago. Such erudite technicalities were not needed to persuade the legislators of 11 states. They responded to chanting crowds who wore T-shirts emblazoned with the words "Laetrile Works, You Bet Your Life". However, a slim majority of the California State Assembly Health and Welfare Committee was unconvinced. They killed the laetrile-legalising bill by a vote of six to five. The bill had passed the corresponding State Senate Committee unanimously. The author of the bill, Mr William Campbell, who for some reason is a member of the senate committee, says he will try again in January. Perhaps a more useful form of legislation would be a constitutional amendment to inhibit state governments from legalising quack remedies.

correspondence

Detecting dead bodies in 1718 and 1976

SIR,—I reported (*Nature* 262, 816 (1976)) that dead bodies of a dog and a cat were detected by the presence of fruit-bodies of an agaric species (*Hebeloma vinosophyllum*) appearing on the ground above the buried bones, and suggested the possibility that a victim of homicide buried in soil could be located by this or similar fungi. In response to a 'Science report' in *The Times* (2 September 1976) summarising my article, Dr Denys W. Tucker, formerly of British Museum (Natural History), informed me of a passage published in 1718, (Aubrey, J. *The Natural History and Antiquities of the County of Surrey* 111, (E. Curll, London 1918)), which contains the following lines (pages 225–26) written by John Aubrey of his visit to Woking in Surrey.

"The Grave-Digger here told me, that he had a Rule from his Father, to know when not to dig a Grave upon a Corps not rotted; which was, when he found a certain Plant about the Bigness of the Middle of a Tobacco-Pipe, which came near the Surface of the Earth, but never appear'd above it. It is very tough, and about a Yard long; the Rind of it is almost black, and tender, so that, when you pluck it, it slips off, and underneath is red; it hath a small Button at Top, not much unlike the Top of an *Asparagus*: Of these sometimes he finds two or three in a Grave. He is sure it is not a *Fern* Root.

He hath with Diligence trac'd to its Root, and finds it to spring from the Putrefaction of the dead Body. . ."

The phenomenon described here is close to what I suggested, but is not exactly the same as that expected of ammonia fungi including the above-mentioned species (Sagara, N. *Contr. biol. Lab. Kyoto Univ.* 24, 205–276 (1975)). "It" reminds us of the rhizomorph, pseudorhiza, or aborted fruit-body produced by certain fungi, but does not fit those of any known ammonia fungi. Further, if we interpret "the Putrefaction of the dead Body" as putrefying corpse, the ammonia fungi would not appear at such an early stage of decomposition.

I have been discussing the matter with some noted mycologists and botanists from the UK and Japan, but so far we have not succeeded in pointing out any possible organism for the structure described by J. Aubrey. I would appreciate receiving suggestions as to what it might be and any similar information from any part of the world.

I thank Dr Tucker for the information, and Drs Roy Watling, Geoffrey C. Ainsworth, Rokuya Imazeki, Siro Kitamura, Osamu Sinoda, and Minoru Hamada for the discussion.

Yours faithfully,

NAOHIKO SAGARA

The twin paradox

SIR,—Tom Wilkie's remark (28 July, page 295) that the resolution of the twin paradox lies in the fact that the equivalence of the twins is destroyed by the necessity for the 'moving' one to reverse his motion continues to ignore the fact, pointed out in my letter in *Nature* of 31 August, 1973, that, if that were so, the equivalence would be maintained during the first half of the journey, before reversal occurs. Hence, in the example there cited, Paul, the 'moving' twin, would reach the distant planet a teenage boy, and the reversal and return would restore him to babyhood. It is not customary in scientific research to ignore such obviously remarkable and important points. Will Mr Wilkie therefore kindly say whether he accepts this necessary consequence of his suggested resolution of the paradox, or agrees with me that it makes such a resolution impossible?

Yours faithfully,

HERBERT DINGLE

Hull, UK

Tom Wilkie replies: I stand by every word of my article and do not accept that the above is a necessary consequence. I am writing to Professor Dingle privately on this matter.

Competition 14 asked for a boring or meaningless paragraph. £10 to E. R. A. Beck of Vienna for these introductory remarks:

The subject to be considered in this session of the symposium is one on which much research has been done, much grey matter has been activated and much fruitful discussion has already taken place. Its importance is well known to all of us here today, whether we face it at the laboratory bench or at an adminis-

trative, policy-making or governmental level. Indeed, the fact that an international organisation has chosen to devote an afternoon to an exchange of information on this topic is sufficient evidence that interest has transcended national boundaries. In some form or other, it affects the developed and the developing countries, the technologically advanced and the less-advanced peoples. There is, as yet, no consensus on a solution, nor indeed on a programme for the coming period. In my talk, therefore, I shall attempt to focus attention on some of the more significant points, and express some humble thoughts of my own as to how we might, together, approach the task of seeking a methodology for tackling this absorbing question, ensuring as we do so that our endeavours will also serve those facing this problem in the nations less well endowed with trained manpower and sophisticated equipment. (Aside, speaker to chairman: "I say, which symposium

is this; 'Advanced techniques in control of the screw-worm fly', or 'Special constraints in seeding methods for MHD generators?')

Honorable mention to J. R. Richards (Tadcaster, North Yorkshire) for a genuine paragraph from *The Mind of Light* by Sri Aurobindo.

Competition 15. The front cover of *Nature* used to carry a quotation from Wordsworth:

'To the solid ground
Of nature trusts the Mind that builds
for aye'.

£10 for the best quotation or verse, serious or humorous, suitable for these days. Entries to Competition 15, *Nature*, 4 Little Essex Street, London WC2 by October 20.

Intercalation complexes of DNA

from Donald Voet

It has now been sixteen years since Lerman proposed that aminoacridine dyes bind to DNA by intercalating between its stacked bases. Since then, numerous other planar aromatic molecules, many of which are potent drugs or mutagens, have been found to bind to DNA in a similar manner. Yet the detailed geometries of these intercalation complexes have hitherto been only poorly defined because of the low quality of the available fibres of nucleic acids complexed with intercalation agents. The situation has been greatly remedied recently by the elucidation of several X-ray crystal structures of self-complementary dinucleoside phosphates in complex with various intercalating agents.

X-ray studies have shown that self-complementary dinucleoside phosphates such as cytidyl-(3',5')-guanosine [CpG] often crystallise as miniature double helices. By this it is meant that the dinucleoside phosphate forms two symmetry-related Watson-Crick base pairs with a neighbouring molecule and that their sugar-phosphate backbones have the conformational parameters found in a double helix. In an intriguing extension of this work Sobell and his coworkers have recently reported the X-ray structures of several intercalation complexes of self-complementary dinucleoside phosphates. These are the 2:2 complex of ethidium with 5-iodouridylyl-(3',5')-adenosine [iodo-UpA] (Tsai *et al.* *J. molec. Biol.* **114**, 301; 1977); the 2:2 complex of ethidium with 5-iodocytidylyl-(3',5')-guanosine [iodoCpG] (Jain *et al.* *J. molec. Biol.* **114**, 317; 1977); the 2:2 complex of 9-aminoacridine with iodoCpG (Sakore *et al.* *Proc. natn. Acad. Sci. U.S.A.* **74**, 188; 1977) and the complex of proflavine with iodoCpG (Seshadri *et al.* *Abstracts Amer. Crystallogr. Assoc. Meeting, Michigan State Univ.* 1977). These complexes, which are all heavily hydrated, have quite different crystal structures from one another. Yet their molecular structures show striking

similarities. In all these structures the dinucleoside phosphates form miniature double helices that intercalate an ethidium or an acridine molecule. Thus the base pairs in these structures are separated by about 6.8 Å which is twice the usual base stacking distance found in the B form of DNA (the usual native form).

The intercalation agents are accommodated in the complex by the unwinding of the miniature double helices from the conformations found in nucleic acid double helices. In doing so all of these dinucleoside phosphates have adopted a rather distinctive sugar puckering pattern in which the ribose sugar of the pyrimidine nucleoside is in the C3' *endo* conformation and that of the purine nucleoside is in the C2' *endo* conformation. The same C3' *endo*-(3', 5')-C2' *endo* puckering alternation has been observed in the pseudo intercalation complex of 9-aminoacridine with ApU (Seeman *et al.* *Nature* **253**, 324; 1975). (In this structure the bases pair in a Hoogsteen arrangement without double helix formation. However the base pairs alternate with 9-aminoacridine molecules as in the foregoing intercalation complexes.) Furthermore, computerised model building studies by Alden and Arnott (*Nucleic Acids Res.* **2**, 1701; 1975) have suggested that the most satisfactory conformation for an intercalation complex of B-DNA incorporates the above puckering alternation.

It has long been known that, at saturating concentrations of intercalating agents, DNA will intercalate one molecule for every two base pairs. This observation has led to the 'neighbour exclusion' model which states that the binding of intercalation agents to DNA is subject to the restriction that adjacent binding sites be unoccupied. This model is neatly rationalised by the requirement of a C3' *endo*-(3',5')-C2' *endo* pucker alternation at the intercalation site. Such an alternation can maximally occur between every second base pair.

The foregoing crystal structures account for solution studies which indicate that ethidium preferentially

binds to sequences of the type pyrimidine-(3',5')-purine. In the above structures there are extensive stacking interactions between the nucleic acid bases and the intercalating molecules. However, model building studies show that in complexes which have these base sequences reversed the degree of ring overlap is much reduced. Presumably these latter complexes are less stable than the former. This result also explains why no intercalation complexes of ApU or GpC have been crystallised.

The various structural features common to the foregoing intercalation complexes, which include an 8° relative tilt of the base pairs towards the wide groove, have prompted Sobell *et al.* (*J. molec. Biol.* **114**, 333; 1977) to propose a detailed model for intercalation complexes of B-DNA. In this model, which is substantially based on computer-generated model building, the helix axis is kinked about the intercalation site by 8° and is unwound by 10°. This latter figure is in reasonable agreement with the results of solution studies of intercalation complexes. In addition the sugars about the intercalation site have the pucker alternation described above.

The structural features of this model have led Sobell *et al.* to extend their model building studies to generate a general model for the kinking of B-DNA. In this model the helix axis is bent by 40° into the wide groove through a conformational change that is made possible by a C3' *endo*-(3',5')-C2' *endo* pucker alternation about the kinking site. Then, depending on the interval along the helix axis of these kinks, various families of supercoiled DNA can be generated and Sobell *et al.* present several striking computer generated drawings of these superhelical DNAs. Perhaps the most interesting of these is the one in which a kink occurs every 10 base pairs. This gives rise to a left-handed superhelical structure that contains 1½ turns per 140 base pairs and has an axial length of 80 Å. These and other structural features make it an attractive model for the DNA in nucleosomes.

The foregoing models result from the great similarities among the four crystalline intercalation complexes reported by Sobell and coworkers. But into many ointments a fly will fall. In this case the fly is in the guise of the crystal structure of a 3:2 complex of proflavine with CpG that is reported by Neidle *et al.* in this issue of *Nature* (page 304). This structure, which results from a collaboration between researchers at Kings College, London, and The Institute of Cancer Research, Philadelphia, consists, in part, of miniature double helices into which proflavine molecules are intercalated. The spacing between adjacent C:G base pairs is the expected 6.8 Å. But what is unexpected and potentially damaging to the plausibility of Sobell's models is the fact that all the sugars are in the C3' *endo* conformation rather than having the C3' *endo*-(3',5')-C2' *endo* pucker alternation. Furthermore the miniature double helix is not unwound relative to the helical conformation of uncom-

plexed RNA-11. Rather, the miniature double helix accommodates the intercalated proflavine molecule by a stretching distortion involving small changes in the backbone and glycosidic torsion angles.

It may be that the structure reported by Neidle *et al.* is simply a red herring. After all, a dinucleoside phosphate could hardly be expected to behave as rigidly as a polynucleotide, especially in its interactions with other molecules. But the same criticism can be levelled at the structures reported by Sobell and coworkers. Furthermore, all of the dinucleoside phosphates discussed here are composed of ribonucleotides and therefore cannot be considered to be ideal models for DNA. (The fact that acridine fluoresces red when complexed with RNA and green with DNA indicates that the acridine molecule senses a difference between RNA and DNA). What is clearly necessary to settle the question of the conformation of an intercalation complex of DNA is the

crystal structure of an intercalation complex of a DNA fragment that is at least four base pairs in length. Rumour has it that there are several groups now attempting to crystallise such a complex.

In a wider sense these studies have shown that 'small molecule' crystallography continues to be a valuable tool in elucidating biological structures. The structures discussed here all contain several molecules in their asymmetric unit and hence are very large according to present day standards for 'small molecules'. Indeed, the asymmetric unit of the 9-aminoacridine: iodoCpG complex, which contains 248 non-hydrogen atoms, approaches the size of some of the smaller proteins whose structures were solved using 'macromolecular' crystallographic techniques (rubredoxin for example has 401 non-hydrogen atoms). Thus it seems that the differences between 'small molecule' and 'macromolecular' crystallographic techniques may soon grow indistinct. □

Elementary particles—a rich harvest

from David J. Miller

A symposium on Lepton and Photon Interactions at High Energies was held in Hamburg on 25–31 August, 1977.

A SCIENTIFIC journalist recently tried to persuade me that high-energy physics was one of the fields of science, and there might be others such as molecular biology, where enough progress has been made for the moment. He could not have maintained such an attitude if he had been at this year's conference. The momentum of progress in the field is unabated, with new and exciting experimental data being matched by a significant growth in theoretical understanding.

Evidence for a fifth quark?

The most exciting result of all came from L. Lederman, whose Columbia Fermilab group have now not only confirmed the Υ (upsilon) bump which they see in muon pairs from proton-proton collisions, but have shown that it is composed of at least two clear resonances, one produced three times more strongly than the other. It is almost certainly another pair of objects like the J/ψ and the ψ' ; but this time the theorists were ready for it. There is even a name for this whole class

of particles—'Onium'. Positronium—the pseudo atom made up from an electron and its antiparticle the positron—has been with us for many years. The ψ and ψ' have been called 'charmonium' because they behave as if they are made of a charmed quark and antiquark. A considerable amount of new evidence was reported on the level-structure of charmonium—not only the familiar J/ψ and ψ' 3S states which couple to e^+e^- by way of a photon, but the 3P states which lie between, and the rather less well established 1S states. A surprise has come as the theories have been refined. The non-relativistic theory of heavy quarks in a potential well had sufficient input from the 1^3S (J/ψ), 2^3S (ψ') and 1^3P that it was possible to predict a 3^3S state above the ψ' , at 3,770 MeV/ c^2 —just above the threshold for pair-producing the charmed D mesons. Experimenters at the e^+e^- storage rings SPEAR in California and DORIS in Hamburg had not investigated this region very carefully because of interest in the complex structure just beyond it from 4,000 to 4,450 MeV/ c^2 . They went back to look for the 3,770 only a few months ago and it was found as a clear signal exactly where predicted. If the upsilon is the next onium then it must be made from a pair of even heavier quarks than the charmed quark, so non-relativistic

potential theory should work even better in this case. As soon as Lederman's talk ended the theorists got out their pencils and paper, and in a talk a few hours later K. Gottfried was able to show that all of the known properties of the upsilon could be accommodated in an onium picture. There is therefore almost certainly a new quark flavour in addition to the everyday 'up' and 'down' quarks, the strange quark and the charmed quark.

More on charm

It is only about a year since it became clear that we had indeed seen charmed particles—the D mesons produced in e^+e^- annihilations. Many new properties of the Ds were reported at Hamburg and also evidence for their strange and charmed relative the F. The pseudoscalar Ds had been hard to separate from the vector D* mesons which decay directly into a D and a pion, but the discovery of the 3,770 has brought an unexpected bonus. It decays strongly into DD pairs, but it is not massive enough to give D*. One can therefore set the energy of the e^+e^- rings at 3,770 and study the rather complicated weak decays of the Ds without any extraneous pions. The other approaches to producing charm have been making slower progress. Neutrino experiments at Fermilab and at CERN are now accumulating large

numbers of events with two muons of opposite sign in the final state, or with a muon and an electron. All properties of these events seem to be consistent with charm's being produced in about 5% of neutrino interactions. So far no wholly satisfactory result has been reported on the production of charmed baryons. The Columbia-Fermilab experiment by Wonyong Lee's group has a clear signal with antilambda and three pions. They should also see something with lambda and three pions but they do not, so the significance of the antilambda signal must be questioned. It seems likely that the bubble chamber neutrino experiments will be the first to establish the existence of charmed baryons, but the results from several groups on strange particles from charmed particle decay are fluctuating wildly due to small statistics and no clear conclusions can yet be drawn.

More signs of τ

For two years now there have been signs from SPEAR and from DORIS that the increase of e^+e^- cross sections at about 4 GeV/ c^2 is due to two thresholds, not just to the charm threshold. M. Perl, using SPEAR, was the first to identify a class of events which have a muon and an electron with opposite signs and in which a great deal of the energy escapes as unseen neutral particles. New detectors at SPEAR and new data from DORIS have confirmed the existence of these events and it looks increasingly convincing that they are caused by a new heavy lepton, the tau (τ), a big brother to the electron and the muon. In particular, the cross section for producing them seems to rise smoothly and steadily from threshold towards the correct asymptotic value for the pair production of spin- $\frac{1}{2}$ particles, with mass about 1,850 to 1,900 MeV/ c^2 , coupled to the photon in the normal way. There was some excitement early in the conference when it seemed that one of the most easily predicted decays of the τ (to a pion and a neutrino) was not seen, but the experimenters looked more carefully at their data and were eventually convinced that there was no anomaly.

Neutrino physics

In neutrino physics the new results from the CERN SPS have come at the same time as the second generation results from Fermilab, with the consequence that some of the odder effects suggested by single experiments in the past can now be seen to have gone away. In particular the Harvard - Pennsylvania - Wisconsin - Fermilab, 'HPWF', suggestion of a threshold effect at neutrino energy of about 40 GeV has not been confirmed by any

Has the *src* gene product been found?

from Robin Weiss

AVIAN sarcoma viruses carry a gene, *src*, which is required for the transformation of fibroblasts and the induction of sarcomas, but which is superfluous for virus replication. Because mutants of *src* have been isolated that are temperature sensitive for the maintenance of the transformed state of the cell, it is widely assumed that *src* codes for a transforming protein. On page 346 in this issue of *Nature*, Brugge and Erikson report the detection of a transformation-specific antigen which appears to be a good candidate for the *src* protein. Sera obtained from rabbits bearing tumours induced by avian sarcoma virus (ASV) react with a protein of 60,000 daltons present in transformed cells, which is unrelated to virion structural proteins. The same protein is found in ASV-transformed avian and mammalian cells, strongly indicating that it is a virus-coded protein. Cells infected with transformation-defective, *src* deletion mutants of ASV do not express this protein; neither could it be immunoprecipitated from cells infected with temperature-sensitive *src* mutants and incubated at the non-permissive temperature.

This is not the first time a transformation-specific antigen has been identified in ASV-transformed cells. There is an extensive literature (reviewed by Kurth *Biomembranes* 8, 167; 1976) on a tumour-specific cell surface antigen (TSSA) to which Brugge and Erikson make no reference. It will be important to see whether the 60,000 dalton protein is related to TSSA.

Several attempts have been made to

identify the *src* gene product by *in vitro* translation of ASV RNA. Pawson, Martin and Smith (*J. Virol.* 19, 950; 1976) were not able to identify any polypeptide present in translation products of the ASV genome that was absent from those of a transformation-defective (*td*) mutant. Two recent reports, however, each claim that two polypeptides of approximately 18,000 and 25,000 daltons can be detected after translation of ASV RNA but not of *td* ASV RNA in the reticulocyte system (Kamine & Buchanan *Proc. natn. Acad. Sci. U.S.A.* 74, 2011; 1977; Beemon & Hunter *Proc. natn. Acad. Sci. U.S.A.* 74, 3302; 1977). The work of Beemon and Hunter is particularly interesting because they have demonstrated by analysis of tryptic peptides that the two polypeptides absent in *td* ASV translation products are unrelated to the precursor polypeptide of the virion core proteins. Since *src* is located near the 3' end of the ASV genome it is not easily translated from undegraded genomic RNA preparations, but selection of smaller fragments containing the poly(A) at the 3' end of the molecule proved effective for the translation of these presumed *src* products.

The antiserum that reacts with the 60,000 dalton polypeptide should be useful for selective precipitation of *in vitro* translation products. In their report, Brugge and Erikson already quote a further paper in press on that subject.

Robin Weiss is a member of staff at the ICRF Laboratories, London.

other group. But there are new effects on a more subtle level which are beginning to be believed because they are seen in so many experiments using very different techniques. Until now it has been usual to interpret neutrino data in terms of the simplest quark-parton picture. This will clearly not work any longer. For some years it had been clear that electron-proton and muon-proton scattering data required important corrections to the simple quark model. Now the same corrections have been shown to apply to the charged current neutrino data. Theorists are very pleased about this, because the kind of correction required is just what would be expected from the more formal theory of quarks—quantum chromodynamics 'QCD'.

Neutral current neutrino data has also been improving rapidly, and it is clear that neutral current interactions producing strongly interacting particles (hadrons) are very well described by the Salam-Weinberg GIM model (see *News and Views* 264, 398; 1976) otherwise known as $SU(2) \times U(1)$. P. Sandars (University of Oxford) gave a status report on the other end of the neutral current field—the search for the atomic effects of interference between the weak neutral current and the electromagnetic interaction. Here there are problems. Sandars's group and a group at Washington State University have performed optical rotation experiments with laser light passing through bismuth vapour. If the Weinberg-Salam model is true, and

has the parameters determined from the hadronic neutral-current experiments, then they should have seen large effects due to these parity-violating interferences. But neither group sees any effect, and they have spent a great deal of time checking both their experimental sensitivity and the theory in order to be sure (*News and Views* 264, 505; 1976).

S. Weinberg and others discussed the meaning of these results. It seems that $SU(2) \times U(1)$ is to the weak interaction what the naive quark-parton model has been to QCD; a first approximation which has fitted a surprisingly large part of the data. Now it will be necessary to enlarge the model to accommodate the new quarks and leptons, the absence of atomic neutral currents and perhaps also whatever it is that is causing trimuon events. The HPWF group still sees these events, though the big new CERN neutrino experiment is not yet claiming a definite effect. There is particular interest in two of the HPWF events in which all three of the muons have been given very large energies. This suggests that they have all come from the 'neutrino end' of a neutrino-nucleus interaction—something which no one was able to explain satisfactorily in the framework of current weak-interaction theory.

Plans for the future

The last morning was devoted to the future ('and its alternatives', a phrase quoted by W. Panofsky of SLAC from a US Government memorandum). Panofsky, and H. Schopper of the host laboratory, reviewed the plans for their laboratories and for their e^+e^- storage rings PEP and PETRA which will start work at about 30 GeV in the centre of mass (15+15 GeV beams) in 1979 and 1978 respectively. There was a fascinating talk from J. W. de Wire of Cornell University on CESR, the 8+8 GeV e^+e^- storage ring, which is being built on a minute budget by the standards of the big laboratories. Cornell is one of the last universities in the world to be able to build its own high energy physics facilities. The record of achievement on their 10 GeV electron synchrotron has been excellent and they are now especially confident of doing a good job with CESR because the upsilon falls right in the middle of their useful range of energies. Schopper described how the energy of DORIS will be extended to reach the upsilon, but the commitment to build PETRA on a very rapid schedule makes it impossible to do this immediately. The usefulness of having more than one laboratory doing e^+e^- physics at the same energy has been illustrated repeatedly not only by the results from SPEAR and DORIS on charm and τ production but also by

the latest results from the lower energy French and Italian machines, DCI and ADONE, which are still a long way from having cleared up the problems which remain in the energy region below 3.1 GeV. This region was left almost untouched in the rush to discover the 'new physics' and the Onium-structure of the old quarks—up, down and strange—is still not understood. These two machines will have to collect much more data before we can hope to sort it out.

Although our ideas of QCD and the weak interaction still leave many questions unanswered, J. D. Bjorken of Stanford drew attention in the final talk to the major discoveries which can be confidently predicted for the next 10 or 20 years. As energies rise, the old fashioned strong interaction and the electromagnetic interaction will have a decreasingly important role compared with the quark-gluon coupling of QCD and the charged and neutral currents of weak interactions. As well as discussing the zoo of new objects which might be produced as this regime is reached, he compared the merits of different types of machine which have been proposed to get there. The clear leader is the large e^+e^- machine LEP, as requested by the European Committee on Future Accelerators (*see News and Views* 267, 12; 1977). It would provide data on almost every major question in particle physics, and would also be able to sit at the mass of the neutral current intermediate boson and become a Z^0 factory—mass producing the Z^0 boson in a resonant mode so that the Z^0 couplings to all the quarks and leptons can be investigated simultaneously. Next in usefulness come high energy pp storage rings. These will give us an idea of effects beyond the range of extrapolation of our theories and at energies which other kinds of machine cannot reach. Cosmic rays have given hints of odd behaviour at tens of thousands of GeV (tens of TeV), but it will be storage rings such as ISABELLE at Brookhaven New York, rumoured to be about to be funded in the next ERDA budget, which will make it possible to take such effects seriously. Fixed target proton machines such as the SPS and the Fermilab machine will always be needed to provide neutrino, muon and hadron beams. The Russians are planning a 3 TeV machine and Fermilab's 1 TeV machine is still going ahead—now named the 'Tevatron'.

In the light of Bjorken's discussion there was some disappointment among many physicists at the current plans for the CERN laboratories near Geneva. The only new project which is being asked for by the directorate is an anti-proton on proton colliding beam facility to be added to the SPS. Yet it

is now well known that the antiquark content of the proton is sufficiently large that a high flux pp machine like ISABELLE should produce much more quark-antiquark physics than any conceivable $\bar{p}p$ machine. The other suggested development for the SPS, an electron ring called CHEEP (though it will cost a little more than the anti-proton facility), has a great deal more theoretical backing. The quark-parton model was evolved in response to the first deep-inelastic electron-proton scattering results. If CERN builds CHEEP it will have a unique tool to investigate many anticipated high energy effects by way of deep inelastic processes which are much easier to understand than quark-antiquark scattering. If CERN does not build CHEEP then it is possible that a proton ring could be added to PETRA instead, but it seems improbable that Germany would maintain its present level of subscription to CERN if it had such an advanced home-based programme.

Despite the inevitable arguments about tactics and despite the knowledge that funds will be hard to find if economic crises continue, there is confidence that the machines after PEP and PETRA will be built within a reasonable period. Bjorken mentioned something which particle physicists feel very strongly; the case for building the next generation of accelerators can be made more precisely and with more confidence now than has been possible for any previous generation of accelerators. Here is a field where progress must continue. □

Recognition of lysosomal enzymes

R. Colin Hughes

IN the late 1960s, Elizabeth Neufeld and her colleagues showed that 'corrective factors' secreted by skin fibroblasts established from normal individuals could eliminate intracellular deposits of mucopolysaccharides that build up in mutant cells established from the skin of mucopolysaccharidoses patients. Such patients lack the particular lysosomal enzymes to catabolise these substances in the normal way (see Neufeld *et al. A. Rev. Biochem.* 44, 357; 1975; Dawson & Lenn in *Handbook of Clinical Neurology* 27, 143; 1976). Later the 'corrective factors' were identified as precisely those lysosomal enzymes missing in each of the mutant cell lines (Bach

R. C. Hughes is a research scientist at the Medical Research Council, National Institute for Medical Research, Mill Hill, London.

et al. Proc. natn. Acad. Sci. U.S.A. **69**, 2048; 1972; Cantz *et al. J. biol. Chem.* **247**, 5456; 1972; von Figura & Kresse *Biochem. biophys. Res. Commun.* **48**, 262; 1972). More recently, Sly *et al. (J. Pediatr.* **82**, 249; 1973) reported a child with a mucopolysaccharide storage disease due to a deficiency of β -glucuronidase whose fibroblasts were corrected by purified bovine or human enzyme (Hall *et al. Archs Biochem. Biophys.* **155**, 32; 1973; Brot *et al. Biochem. biophys. Res. Commun.* **57**, 1; 1974). Since lysosomal enzyme deficiencies produce severe problems for the patients the encouraging idea of an enzyme replacement therapy prompted by these experiments has been pursued vigorously. Such efforts are likely to be aided by the impressive progress being made in showing how lysosomal enzymes added externally to cells find their way to the abnormal intracellular storage materials.

This process involves specific pinocytosis and apparently utilises part of the normal life cycle of these enzymes, which according to Hickman and Neufeld (*Biochem. biophys. Res. Commun.* **49**, 992; 1972) are first secreted to appear on the outside of cells and are then quickly taken up again by the same or adjacent cells to perform their enzymic function. Just why the lysosomal enzymes go through this complicated scheme is completely unknown. The important point is that one step in the proposed scheme involves recognition by fibroblast cell surface receptors. Some of the molecular features of this recognition are becoming clearer and there are several surprises.

The removal of carbohydrate from human β -hexosaminidase, which like most lysosomal hydrolases is a glycoprotein, was found to abolish its uptake by fibroblasts and led to the idea that recognition of the enzyme by fibroblasts involves a carbohydrate moiety (Hickman *et al. Biochem. biophys. Res. Commun.* **57**, 55; 1974). The classic work of Ashwell and Morell had already shown that carbohydrate specificity was critically involved in recognition of glycoproteins by mammalian liver, a reaction that explained the rapid clearance of these glycoproteins from the circulation. The properties of the liver cell receptor are such that only glycoproteins with terminal galactose residues are recognised and taken up by the hepatocyte (see Ashwell & Morell *Trends in Biochemical Sciences* **2**, 76; 1977 for recent discussion). Although the concept is clearly similar this receptor is sharply distinguishable from the receptor on fibroblasts which mediates the uptake of lysosomal hydrolases. The clearest evidence on the molecular

detail of this interaction so far has been obtained by Sly and his colleagues using human β -glucuronidase.

Previous studies (Glaser *et al. Archs Biochem. Biophys.* **166**, 536; 1975; Brot *et al. Biochem. biophys. Res. Commun.* **57**, 1; 1974) had shown that the enzyme appeared in two forms separable by a charge difference. Only the more acidic form, concentrated particularly in platelets but relatively scarce in placenta, was taken up by skin fibroblasts established from the patient with β -glucuronidase deficiency. At the recent ICN-UCLA meeting on Cell Surface Carbohydrates and Biological Recognition in Keystone, Colorado, Sly reported (*J. supramol. Structure Supplement* (1977) in the press) the competitive inhibition of β -glucuronidase uptake by certain yeast mannans containing phosphate and by simple hexose phosphates, in particular D-mannose-6-phosphate. Furthermore, the high uptake form of the enzyme was converted to a less acidic low uptake form without loss of enzymic activity by treatment with highly purified alkaline phosphatase. More detailed reports (Kaplan, Archord & Sly *Proc. natn. Acad. Sci. U.S.A.* **74**, 2026; 1977; Kaplan, Archord & Sly *J. clin. Invest.* (1977), in the press) substantiate these suggestions for a novel receptor on fibroblasts that recognises hexose phosphate on the lysosomal glycoproteins β -glucuronidase, β -hexosaminidase and β -galactosidase. The same kind of recognition is involved in the uptake of acidic forms of β -glucuronidase from liver, urine, spleen and placenta and the hexosaminidase secreted by normal human fibroblasts also seems to contain the phosphohexosyl group for the fibroblast receptor.

Phosphorylated sugars are very rarely found in mammalian glycoproteins. The sensitivity to alkaline phosphatase suggests a phosphomonoester, similar perhaps to some forms of haemoglobin which contain terminal D-glucose-6-phosphate residues (Haney & Bunn *Proc. natn. Acad. Sci. U.S.A.* **73**, 3534; 1976). Davis *et al. (FEBS Lett.* **65**, 3035; 1976) recently reported the isolation of phosphoglycoproteins from rat brain and demonstrated phosphomannosyl residues. Although phosphomannosyl is a well known constituent of yeast glycoproteins, this is the first example found in mammalian glycoproteins.

Other workers (Hieber *et al. Biochem. biophys. Res. Commun.* **73**, 710; 1976; Fedn *Proc.* **36**, 653; 1977) have been interested mainly in β -galactosidase and believe mannose also regulates uptake of this enzyme by fibroblasts. Whether the mannose residues are phosphorylated is not yet clear. Hieber *et al.*, concluded that this

was a distinct uptake system different from that which mediates β -glucuronidase uptake. Hieber *et al.* have, however, shown that the glycopeptides (carbohydrate chains containing just one or two amino acid residues) inhibit assimilation of β -galactosidase by fibroblasts. The exciting implications of these findings are that such glycopeptides could serve as recognition markers to get proteins rather specifically and efficiently into cells and perhaps opens up the possibility of enzyme replacement therapy in diseases in which a 'high uptake' human enzyme is not readily available.

Several questions concerning the role of the fibroblast surface receptor in lysosomal organisation are raised by these findings. It has been known for many years that β -glucuronidase for example is bound to the inner surface of the lysosomal membrane. Is the same recognition marker used for this interaction as that involved in pinocytosis? This is a distinct possibility since the inner surface of the lysosomal membrane (presumably carrying the specific receptor protein) appears on the outer surface of the cell during lysosomal discharge in the model of Hickman and Neufeld (*op. cit.*). Second, does the fibroblast surface receptor play a part in controlling the levels of extracellular and potentially lethal lysosomal enzymes? This may be so but collateral evidence has revealed yet another recognition system which, like that already discussed, involves mannose-rich carbohydrate chains of glycoproteins but does not require these residues to be phosphorylated.

When rat lysosomal enzymes are injected intravenously in rats they are cleared from the circulation within a few minutes (Stahl *et al. Nature* **264**, 86; 1977; *Proc. natn. Acad. Sci. U.S.A.* **73**, 4045; 1976) and end up in the liver. The system is clearly different from the clearance of galactose terminal glycoproteins, desialysed orosomucoid, by the Ashwell-Morell system which resides in hepatocytes, since there is no inhibition of lysosomal enzyme clearance by orosomucoid unless both terminal sialic acid and galactose residues are removed to expose N-acetylglucosamine terminals. According to Sly *et al. (Fedn Proc.* **36**, 653; 1977; *Biochem. biophys. Res. Commun.* **77**, 409; 1977) clearance of human placenta β -glucuronidase in the rat was similar to that reported by Stahl *et al. (op. cit.)* for rat enzymes, and the liver clearance system was shown to involve Kupffer cells rather than hepatocytes. This clearance system was inhibited even better by mannose terminal glycoproteins than by N-acetylglucosamine terminal glycoproteins. Clearance of N-acetylglucosamine terminal glycopro-

teins was antagonised by simultaneous injection of mannose terminal glycoproteins and *vice versa*, suggesting that there are unlikely to be independent Kupffer cell receptors responsible for clearance of mannose or N-acetylglucosamine-terminal glycoproteins respectively. Presumably the Kupffer cell receptor has relaxed specificity and binds to mannose residues present in both glycoprotein types. It has recently been suggested that the hepatocyte receptor also does not discriminate between galactose and glucose terminals in some circumstances (Stowell *et al.* *Fedn Proc.* **36**, 653; 1977). In this property the mammalian receptors resemble the plant lectins which in general also bind to several different sugars. Since both forms of β -glucuronidase are efficiently cleared from the circulation, the Kupffer recognition system does not require a phosphorylated site on the lysosomal enzyme, raising fascinating speculation on the potential role of phosphorylation in

deciding the circulatory fate and target cell of glycoproteins.

In summary, therefore, the original findings of Ashwell and Morell have opened up to reveal a remarkable collection of cellular receptors for glycoproteins. These receptors differ in specificity according to cell type, for example the preference of the mammalian hepatocyte receptor for galactosyl terminals, the Kupffer and fibroblast cell receptors for mannosyl residues and phosphomannosyl residues respectively while the identification of the avian hepatic receptor as a binding activity for N-acetylglucosaminyl terminated glycoproteins (Lunney & Ashwell *Proc. natn. Acad. Sci. U.S.A.* **73**, 341; 1976) warns against extrapolation across species. The list almost certainly will continue to grow and underlines the feeling that carbohydrate structure is involved in a variety of recognition systems, and defects in such recognition may correlate with some human disease states. \square

Diffusion in polymers

from Paul Calvert

SEMICRYSTALLINE polymers behave as if they consisted of two phases, crystal and amorphous, arranged in alternate layers. Most simple properties are a function of the fractional crystallinity but are insensitive to the structure or arrangement of the phases. Some recent measurements on the diffusion of chain molecules in polyethylene serve as a reminder that diffusion can tell us about structural details.

According to the two-phase model a semicrystalline polymer consists of plate-like crystals of about 10 nm thickness separated by amorphous regions of the same size. The crystals have the same properties as hypothetical large crystals and the amorphous material should be the same as completely amorphous polymer. This idea works well for bulk properties such as density, modulus, heat capacity and expansion coefficient (see Wunderlich *Macromolecular Physics I*, Academic Press, 1973). There are probably crystal defects and special crystal surface structure but they do not affect bulk properties.

It seems reasonable that motion in the amorphous phase will be limited by the crystals, but in polymers such as polystyrene and polyethylene terephthalate I am not aware of any evidence for a change in glass transition temperature or mobility between com-

pletely amorphous and partly crystalline polymers. Boyer has suggested that this happens in polyethylene (*Macromolecules* **6**, 288; 1976) but the situation is still confused. Intercrystalline links are chains running from one crystal to another stitching the structure together (Keith & Padden *J. appl. Phys.* **42**, 4585; 1971). These should be more frequent in quickly cooled samples where the crystals are small and have proved useful in explaining effects of molecular weight and cooling rate on mechanical properties. Unfortunately, no very convincing way of detecting them in normal samples has been found (although see Wunderlich *Makromol. Chem.* **175**, 977; 1974). So, although strength and deformation behaviour do depend on structural factors other than crystallinity, and although likely factors have been discussed, there is not much supporting evidence. Diffusion measurements could be very informative about this.

Many measurements of diffusion of gases in polymers were made in the 1950s and early 1960s when plastic packaging was becoming important (see Crank & Park *Diffusion in Polymers* Academic Press, 1968; Rogers in *Physics and Chemistry of the Organic Solid State* **2**, Interscience 1965). It is probably these workers whom we should thank for the disappearance of the soggy potato crisp. In semicrystalline polymers it was found that gas solubilities were proportional to the

amorphous fraction, implying that gases are excluded from the crystals. Michaels and coworkers (*J. Polymer Sci.*, **41**, 53; 1959; **50**, 393, 413; 1961) described diffusion by $D = D_a / \tau \beta$ where D_a is the diffusion coefficient in pure amorphous material, τ is a 'tortuosity factor' dependent on crystallinity and β is an immobilisation factor which is dependent on the size of the diffusing molecule. They initially found that in branched and Ziegler polyethylenes τ was proportional to amorphous content to a power between -1 and -2 rather than the expected inverse proportionality. In later measurements on linear polyethylene (*J. appl. Phys.* **35**, 3165; 1964) they did find diffusion to be simply proportional to amorphous content in samples crystallised by cooling. By annealing, however, they could produce samples of the same crystallinity but with different diffusion rates. This topic has essentially remained in this state since.

Klein and Briscoe made measurements of the diffusion of long chain amides in polyethylene (*Nature* **257**, 386; 1975; *Polymer* **17**, 481; 1976), and have recently extended this to study morphological effects on the diffusion of chain molecules (*Nature* **266**, 43; 1977; *J. Polymer Sci. (Phys.)* (in the press)). They envisage the diffusion of a chain molecule in the interlamellar regions as the motion of a large snake across the floor of a forest, winding amongst the intercrystalline links. This is based on the ideas of de Gennes (*J. Chem. Phys.* **55**, 572; 1971; *J. de Physique* **36**, 1199; 1975), and monte carlo calculations for two dimensional snake-like diffusion ('reptation') around obstacles by Doi (*J. Phys. A* **8**, 417; 1975). With some rather sweeping assumptions about the frequency of intercrystalline links they are able to calculate relative diffusion rates for two compounds containing 45 and 25 carbon atoms in rapidly and slowly cooled samples. The calculated ratios are in respectable agreement with experiment. The calculated and observed diffusion rates are faster in the more crystalline, slowly cooled, sample in contradiction to the results of Michaels for gases, and to simple crystallinity theories.

At the moment this is a lot of theory based on little data, and there are many unanswered questions including why annealed samples are different from continuously cooled ones, why Eby found more rapid diffusion in film surfaces (*J. appl. Phys.* **35**, 2720; 1964) and whether diffusion is homogeneous throughout the spherulites. Nonetheless, a quantitative theory is much better than a qualitative model and we should learn a great deal about morphology in proving it right or wrong. \square

review article

Mathematical models in applied ecology

Gordon R. Conway*

Since the 1950s there has been a growing interest in mathematical models as guides to harvesting fish and game or controlling pests and vector borne disease. So far there are few indications that we can use such models in day-to-day ecological management, but experience confirms that they have a powerful role to play in developing management strategies and in the formulation of policy.

CONTEMPORARY research in applied ecology can be criticised on several counts: it is predominantly empirical, the effort is fragmented into different fields and there is little attempt to link economic and social factors with ecological factors. These criticisms are by no means new. That they have to be repeated is a reflection of the considerable complexity of most problems in applied ecology and the very real intellectual and practical difficulties of integrating principles derived from pure ecology with principles arising out of the social sciences.

In the 1960s Watt laid the foundations for a coherent theory of applied ecology¹. His starting point was the perception that all natural resource management fields are related to one another by common dependence on the science of ecology, and by a common concern with the problem of optimisation. He also recognised that they are universally characterised by processes such as dispersal, predation, competition and weather effects whose mathematical properties are typically non-linear and complex. The development of a theory thus also required the elaboration of a common set of analytical tools and mathematical models.

Watt's pioneer efforts stimulated the development of a wide range of applied ecological models²⁻⁶. For the most part these, and earlier models, have been aimed at answering questions of strategy. Built on knowledge derived from the study of undisturbed organisms in their natural environment, they have been directed at the strictly ecological problems of maximising harvests of domesticated or wild animals and plants and minimising populations of pests and diseases. Underlying their development there has often been a conscious search for those natural thresholds and non-linearities in the dynamics of populations which can be successfully exploited for harvesting or control. At their best these models have become powerful didactic tools, guiding research and determining policy.

Strategic models, however, are purely ecological in orientation with no economic and social component. True policy models, which explicitly include these components, have so far been developed largely for fisheries, although in recent years they have begun to appear in the field of pest control. They are, of course, considerably more complex than strategic models but the few successful examples graphically demonstrate the critical importance of understanding the consequences of the interaction between the biological non-linearities of a system and those introduced by economic factors.

More recently, a third kind of model has appeared bearing on the day-to-day decisions involved in the harvesting or control of a specific population. Such tactical models have the formidable task of coping in some detail not only with temporal and spatial heterogeneity, but also with the weather variables which tend to be dominant at the tactical level. As a consequence most are

formulated as computer simulations. So far, very few, if any, have shown practical success.

Together, strategic and policy models may be able to correct the deficiencies of much of today's applied ecological research, by providing a stronger theoretical base, a sense of coherence between the different fields and an understanding of the nature of the policy questions and their answers. That may in turn lead to tactical models for use in everyday management.

This review begins with a brief historical note, which is followed by a discussion of the relative merits of small and large scale modelling in applied ecology. The main body of the review examines the relative progress of policy, strategic and tactical models in the harvesting of fish and game and the control of pests and vector borne disease.

Early models

The origins of contemporary modelling lie in nineteenth-century epidemiology⁷ and demography⁸ models. From the former there is a direct link to the model of malaria transmission developed by Ross at the beginning of this century⁹⁻¹². His original work was of enormous significance not only in epidemiology but also in the broader field discussed here because he clearly established the critical implications of the non-linearities in the system for control strategies (D. J. Bradley, inaugural lecture at the London School of Hygiene and Tropical Medicine). The model demonstrated that malaria could theoretically be eradicated without the need to eradicate the mosquito population as had previously been supposed: there was a critical threshold below which transmission of the malaria parasite ceased.

The nineteenth-century demographic models provided the basis for early theoretical studies of harvesting strategies. In the 1930s Graham¹³ and Hjort *et al.*¹⁴ independently drew attention to the management implications of the logistic equation as a model of population growth:

$$dx/dt = F(x) = rx(1 - x/K) \quad (1)$$

where r is proportional growth rate and K is the asymptotic stable equilibrium, traditionally referred to as the carrying capacity of the population environment. For this model the maximum sustainable yield (MSY) of, say, a fish population is obtainable by harvesting at a level $x = K/2$.

In subsequent decades few useful extensions were made to this basic work; it was not until the 1950s that progress was made with the development of a new generation of malaria and fish harvesting models and the first attempts to model agricultural and forest pests.

Large scale modelling

At the same time many ecologists became interested in the ability of modern computers and computer languages to mimic in detail

*Centre for Environmental Technology and Department of Zoology and Applied Entomology, Imperial College of Science and Technology, London SW7, UK.

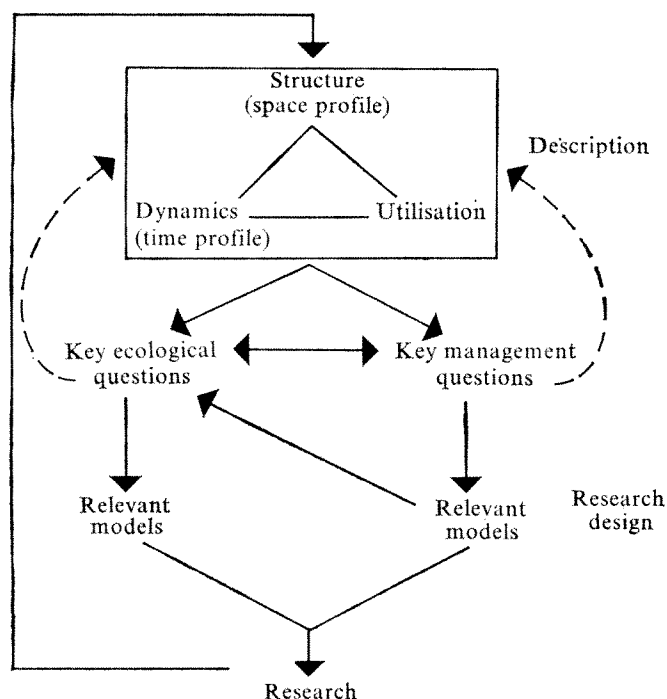

Fig. 1 A suggested procedure for applied ecosystem analysis, designed for a multidisciplinary team working on a continuing seminar basis. The procedure although flexible, is intended to ensure that ecological and management issues are raised simultaneously³⁶.

the dynamic and structural complexity of ecological systems¹⁵⁻¹⁹. This interest played an important part in the evolution of the International Biological Programme²⁰⁻²³ and in several of the IBP biome studies a central role was given to large scale ecosystem models.

A common approach to ecosystem modelling, both in the IBP and elsewhere has been to define ecosystems in terms of series of compartments—producers, consumers and decomposers, and an abiotic compartment—linked by equations describing energy (carbon) flows and materials cycling. The resulting models are essentially mechanistic, the hope being that the sum effect of the modelled interactions between and within compartments is sufficient to provide predictions of changes in the ecosystem, particularly the biomass of its constituent species, over relatively short periods.

A final assessment of the biome models would be premature now, since with some exceptions²⁴⁻²⁷ the relevant documentation is unpublished. There is no doubt that the models have conferred a better understanding of the complexity of ecosystem structure and dynamics, particularly on those engaged in the construction of the models^{21,28}. But so far there is little evidence that they have been useful in answering specific management questions²⁹. More successful in this respect have been aquatic ecosystem models which have taken both biotic and water quality into consideration, using mass balance equations^{30,31}. These can be used, for example, to assess the effects of the siting and quality of waste water discharges on rivers, lakes and other bodies of water. In general, though, while energy and material budgeting provides a convenient basis for linking ecosystem components the resulting models cannot easily be used by policy makers and managers whose prime concerns are the monetary and social outcomes of manipulating ecosystems. In practice, management issues are best served by purpose-built models³²⁻³⁴.

The alternative approach is not to attempt, at least at first, to match complex ecosystems with complex models³⁵, but to assume that their essential structure and behaviour can be understood and predicted through a limited number of key processes and that management problems can similarly be solved by altering a few key decisions³⁶. The task of the applied ecologist then becomes that of identifying the key questions and of choosing such appropriate mathematical models as will provide the answers (Fig. 1).

This approach, with its explicit avoidance of large-scale models, carries no guarantee that important features of the ecosystem will not be missed. However, in the absence of holistic models which are both sufficiently realistic and tractable it is probably more fruitful to concentrate on smaller-scale models designed to answer specific chosen questions, relying on multi-disciplinary interaction and the use of various graphic and flow diagram techniques to provide a holistic framework for the question posing. There is a greater likelihood of building models which are both practical and likely to contribute significantly to the emerging body of theory.

The remainder of this review is devoted, with some exceptions, to models which are based either implicitly or explicitly on these assumptions.

Vector borne disease

The new malaria model^{37,38} produced by Macdonald in the 1950s was based on that of Ross but was more biologically realistic, for example incorporating the possibility of superinfection. Central to the model is a function for the rate of malaria reproduction, for stable populations and static epidemiological conditions, of the form

$$Z_0 = bC/r \quad (2)$$

where Z_0 is the basic reproduction rate of malaria, or the number of infections distributed in a community as a direct result of the presence of a single, primary non-immune case, b is a measure of the probability of a human becoming infected if he is bitten by a mosquito with sporozoites in its glands, r is the recovery rate in man and C , the vectorial capacity

$$C = \frac{ma^2p^n}{\ln(1/p)} \quad (3)$$

where m is a measure of the density, a the man biting rate and p the daily survival rate of the mosquito population, and n the length of the parasite cycle in the mosquito.

Formulated like that the model is an elegant and powerful didactic tool with important implications for the broad strategies of malaria control. Simple inspection of the model reveals that strategies of killing larval mosquitoes, or administering prophylactic or curative drugs have a linear effect on the malaria reproduction rate, through their respective impacts on the terms m , b and r . However the strategy of insecticide spraying against the adult mosquitoes not only lowers m but also reduces p , and since this term enters the function non-linearly, small reductions in p result in disproportionately large reductions in the reproduction rate. This insight has been important in justifying the reliance on adulticide spraying as a principal malaria control strategy since World War II.

More recently, however, an attempt to use Macdonald's model to guide a local field control project has met with failure³⁹. Simulation studies⁴⁰, were used to prescribe the specific tactics for a strategy of chemotherapy combined with DDT spraying, aimed at interruption of malaria transmission in the Kankiya district of North-Central Nigeria, where earlier campaigns had failed. Part of the subsequent failure of the project was due to operational problems; the insecticide spraying was seriously delayed and proved ineffective against the particular vector population, *Anopheles gambiae*. It also became clear, however, that there were fundamental problems in the formulation and application of the model. The problems, moreover, seem similar to those encountered when attempts have been made to use models for tactical decisions in other fields such as fish harvesting or agricultural and forest pest control.

First, Macdonald's model is too aggregated and thus ignores both spatial heterogeneity and the important population subdivisions of age and state; the parameter b , for example, subsumes a complex of different biological processes including the host immune response which results in different immunological classes in the human population. Second, even when parameters seem

Fig. 2 Dynamics of Schistosome transmission based on elaboration of Macdonald's model. The two isoclines for stationary mean worm load (1) and fraction of snails infected (2) intersect at two stable points and at an unstable 'breakpoint' M_B below which the disease goes to extinction⁴⁷.

valid and well defined, the survival rate p for example, they are often difficult to measure with accuracy in the field. Third, being essentially deterministic and designed for stable populations, the model is not appropriate for the specific local conditions in Nigeria which are characterised by a seasonal and explosive epidemics.

Reviewing this episode Najera³⁹ acknowledges the value of Macdonald's model in its time but argues for the development of a third generation of malaria models, reflecting greater biological realism and the change from the objective of malaria eradication to malaria control. A deterministic model developed by Dietz *et al.*⁴¹ which recognises seven distinct epidemiological classes in the human populations is a step in this direction. As with earlier models a threshold vectorial capacity is specified below which malaria cannot maintain itself, but unlike Macdonald's model, where 100% endemicity is rapidly reached once the threshold is passed, the immune mechanism now realistically regulates the endemic level, and the model thus provides a truer measure of control in terms of the reduction in endemicity. Partial field tests have been applied to the model and it is currently being used to evaluate control strategies.

Schistosomiasis has recently received increasing attention from mathematical modellers⁴²⁻⁵². The disease is considerably more complex and much of the modelling effort has been focused on specific components of the disease cycle. There have, however, also been significant attempts to uncover the non-linearities in the overall life cycle of the disease which involves the transmission of the schistosome worms between the human and snail host. The classic model is again due to Macdonald⁵¹ who demonstrated the existence of a theoretical threshold or 'breakpoint' in the mean worm load in man, below which the disease goes to extinction (Fig. 2). The model further revealed that the threshold condition is more sensitive to changes in the probability of transmission from snail to man than man to snail and led him to suggest that the strategic priority should go to ensuring safe water supplies rather than improved sanitation. Macdonald's results have been modified by several subsequent workers: Bradley and May^{47, 52}, for example, have shown that the assumption of a non-random distribution of worms in man significantly alters the threshold criteria.

May also observes that further non-linearities are likely to be introduced in the schistosome model once the economic costs of control are considered. So far no-one has attempted to combine economic and ecological features in a vector borne disease model,

although cost-benefit estimates have been derived for a number of situations⁵³⁻⁵⁶. Such estimates tend to be unsatisfactory because of the difficulty of obtaining realistic measures of benefits which in many cases are intrinsically unquantifiable. Loss of earning capacity as a result of morbidity or mortality can be calculated but there remains the problem of translating this loss into actual benefits following control, given the prevailing pattern of high unemployment and underemployment in the less developed countries. For the present it is more important to incorporate costs alone into epidemiological models, in particular so as to illuminate the changing cost pattern of a control or eradication campaign as it nears its objectives. The recent collapse of several malaria control campaigns suggests insufficient understanding of how maintenance costs and operations are determined by the epidemiological features of low endemicity. A related issue is the interaction of control campaigns for different diseases and the question of when it is 'safe' to switch budget priorities from one control campaign to another.

Harvesting

Policy models which integrate ecological and economic factors have been most successfully developed for fishery harvesting⁵⁷. This is partly due to the ease with which the basic logistic model used to describe fish population growth can be manipulated and extended⁵⁸⁻⁶⁰. Despite, or perhaps because of, its simple assumptions it has proved a powerful tool for illuminating fishery policy issues. The success of the 1946 Overfishing Convention has been attributed in part to Graham's forceful arguments based on the model⁶¹.

In the 1950s Schaefer⁶² incorporated fishing effort into the basic equation

$$dx/dt = rx(1 - x/K) - qEx \quad (4)$$

where E is effort (for example vessel-days per unit time) and q the catchability coefficient. Gordon⁶³ then completed the economic formulation

$$\pi(x, E) = pqEx - cE \quad (5)$$

where $\pi(x, E)$ is net economic revenue, p and c are unit price and

Fig. 3 Instability of supply and demand in the open access fishery as revealed by the Schaefer model. For demand curve D_1 , the equilibrium is at (2) or (4) depending on the starting population. However, a slight demand shift to D_3 results in inevitable overfishing (5)⁵⁷.

Fig. 4 Present value curves for blue whale harvesting at 5% and 10% discount rates. The total present value (TPV) is the sum of the net depletion revenue (π_1) obtained from depleting the initial stock (100,000) to the sustained yield level, and the present value of that sustained yield ($PV(\pi_s)$). Using a simple Schaefer model the MSY would be at 75,000 whales equilibrium population⁷¹.

cost, and used the model to show that in the open access fishery uncontrolled effort leads to an equilibrium at which total revenue equals total cost, so that the economic rent is completely dissipated. More recently several workers have extended his analysis to incorporate questions of supply and demand. For the open access fishery the supply curve for sustained yield is of the form

$$Y = rc(1 - c/pK)/p \quad (6)$$

High prices thus lead to biological overfishing. If the elasticity of demand is also taken into account the instability of the system becomes even more apparent (Fig. 3)^{57,64,65}.

The Schaefer model has played an important part in attempts to introduce some degree of regulation in otherwise open access fisheries. It provided, for example, one argument which led to the 1966 ban on blue whale harvesting^{66,67} and, in modified form, is currently used in calculating maximum sustainable yields (MSYs) and catch limits for all currently exploited whale stocks.

In the last two years, however, a number of criticisms have been levelled at fishery policy based on setting MSYs and catch quotas in this fashion¹²². One criticism stems from the deterministic nature of the models used. Beddington and May⁶⁹ demonstrate that in a randomly fluctuating environment the relative variability in population magnitude and hence yield increases systematically as harvesting effort increases. Moreover this effect is more pronounced when management is based on constant catch quotas rather than on a direct regulation of effort.

A more fundamental criticism is that the economic analysis ignores the important capital component in fishery management. As Clark and Munro^{57,70} forcefully point out a fishery is a capital asset and by definition its value is equal to the present value (PV) of the net future revenues it is expected to yield. In practice the commercial fishery aims not for an MSY but to maximise

$$PV = \int_0^{\infty} e^{-\delta t} - \pi(x, E) dt \quad (7)$$

where δ is the continuous discount rate per annum.

Clark has illustrated the practical consequences of this assumption in terms of blue whale harvesting⁷¹, where the maximum total present value is obtained at a stock level well below the MSY derived from a simple Schaefer model (Fig. 4). This result arises because the intrinsic rate of increase, r , of whale populations is of the order of 5–10%, which is similar to or often less than prevailing commercial discount rates. In many commercial fisheries the bionomic growth rate δ/r is less than unity and the MSY is a sensible first approximation to a management goal but where δ

exceeds r , conservation can only be achieved by decisions which, in effect, replace the high commercial discount rate by a politically derived social rate.

As a practical management tool the Schaefer model is also too dependent on the availability of a long run of catch data. It may be the only approach where age grading of fish is impossible but for the majority of commercial fish an age class model is feasible and indeed essential if the detailed population dynamics, and in particular any non-linear stock-recruitment phenomena, are allowed for adequately. The first significant advance in this direction was the Beverton and Holt model⁷² which gives the annual biomass yield Y in equilibrium for a population consisting of cohorts of all ages

$$Y = R \exp(F t_{\mu}) \int_{t_{\mu}}^{\infty} \exp(-(M + F)t) w(t) dt \quad (8)$$

where R is annual recruitment, F and M the fishing and natural mortality coefficients, $w(t)$ the weight which is usually computed by the von Bertalanffy function and μ is the mesh size, so that t_{μ} is the age when fish are first caught. The model can thus be used to prescribe management strategies in terms of fishing mortality and mesh size. Its main application has been for North Sea demersal fish stocks. Beverton and Holt recommended a mesh size of the order 110 mm for plaice and haddock with a 80–90 mm mesh to ensure survival of sole and whiting, and by the early 1960s minimum mesh sizes of that order were in operation in the North Sea⁶⁶.

More recently, the Leslie matrix formulation^{73–76} has been used to represent the age structure of fish and game populations subject to harvesting

$$\mathbf{x}_{i+1} = \mathbf{A} \mathbf{D} \mathbf{x}_i \quad (9)$$

the matrix \mathbf{A} having elements
